A COMPREHENSIVE TREATISE ON INORGANIC AND THEORETICAL CHEMISTRY

VOLUME VIII

N, P

BY THE SAME AUTHOR

A COMPREHENSIVE TREATISE ON INORGANIC AND THEORETICAL CHEMISTRY

In Sixteen Volumes. With Diagrams.

Vol. I.	H, O.
Vol. II.	F, Cl, Br, I, Li, Na, K, Rb, Cs.
Vol. III.	Cu, Ag, Au, Ca, Sr, Ba.
Vol. IV.	Ra and Ac Families, Be, Mg, Zn, Cd, Hg.
Vol. V.	B, Al, Ga, In, Tl, Sc, Ce, and Rare Earth Metals, C (Part I).
Vol. VI.	C (Part II), Si, Silicates.
Vol. VII.	Ti, Zr, Hf, Th, Ge, Sn, Pb, Inert Gases.
Vol. VIII.	N, P.
Vol. IX.	As, Sb, Bi, V, Cb, Ta.
Vol. X.	S, Se.
Vol. XI.	Te, Cr, Mo, W.
Vol. XII.	U, Mn, Ma, and Re, Fe (Part I).
Vol. XIII.	Fe (Part II).
Vol. XIV.	Fe (Part III), Co.
Vol. XV.	Ni, Ru, Rh, Pd, Os, Ir.
Vol. XVI.	Pt. and General Index, completing the work.

MELLOR'S MODERN INORGANIC CHEMISTRY.
Revised and Edited by G. D. Parkes, M.A., D.Phil., in collaboration with J. W. Mellor, D.Sc., F.R.S.
With numerous Illustrations.

A COMPREHENSIVE TREATISE ON

INORGANIC AND THEORETICAL CHEMISTRY

BY

J. W. MELLOR, D.Sc., F.R.S.

CONTENTS OF VOLUME VIII

CHAPTER XLIX

NITROGEN

§ 1. The Composition of the Atmosphere (1); § 2. The Physical Properties of Air (22); § 3. The Discovery of Nitrogen (45); § 4. The Occurrence of Nitrogen (46); § 5. The Preparation of Nitrogen (48); § 6. The Physical Properties of Nitrogen (53); § 7. The Solubility of Nitrogen (75); § 8. The Chemical Properties of Nitrogen (79); § 9. Allotropic Forms of Nitrogen (83); § 10. The Valency of Nitrogen (89); § 11. The Atomic Weight of Nitrogen (94); § 12. The Nitrides (97); § 13. The History of Ammonia (144); § 14. The Occurrence of Ammonia (146); § 15. The Preparation of Ammonia (148); § 16. The Physical Properties of Ammonia (173); § 17. The Solubility of Ammonia (194); § 18. The Chemical Properties of Ammonia (205); § 19. The Constitution of the Ammonium Compounds and the Ammines (228); § 20. The Metal Ammines, or Metalammoniates (243); § 21. The Substituted Ammonias—The Amines, Amides, and Imides (252); § 22. Analogies between Liquid Ammonia and Water (276); § 23. Hydroxylamine (279); § 24. The Salts of Hydroxylamine (300); § 25. Nitrohydroxylaminic Acid (305); § 26. Hydrazine or Diamide (308); § 27. The Salts of Hydrazine, or Hydrazonium Salts (322); § 28. Hydrogen Azide, Hydrazoic Acid, or Azoimide (328); § 29. The Azides, Azoimides, Trinitrides, Hydrazoates, or Pernitrides (344); § 30. The Fixation of Atmospheric Nitrogen by Organisms (356); § 31. The Fixation of Atmospheric Nitrogen by Direct Oxidation (365); § 32. Nitrogen Oxides—Nitrous Oxide or Hyponitrous Oxide (382); § 33. Hyponitrous Acid (404); § 34. The Hyponitrites (410); § 35. Nitric Oxide (417); § 36. Nitrogen Trioxide (449); § 37. Nitrous Acid (454); § 38. The Nitrites (470); § 39. Nitrogen Peroxide or Tetroxide (529); § 40. Nitrogen Pentoxide (550); § 41. Nitric Acid—History and Occurrence (555); § 42. Nitric Acid—Preparation (558); § 43. The Composition of Nitric Acid and its Hydrates (563); § 44. The Physical Properties of Nitric Acid (568); § 45. The Chemical Properties of Nitric Acid (582); § 46. The Halogen Compounds of Nitrogen (598); § 47. Nitrosyl Halides (612); § 48. Nitroxyl or Nitryl Halides (622); § 49. Nitrogen Sulphides or Sulphur Nitrides (624); § 50. Amidosulphinic Acid and its Salts (632); § 51. Amidosulphonic Acid and its Salts (637); § 52. Imidosulphinic Acid and its Salts (645); § 53. Imidosulphonic Acid and its Salts (647); § 54. Thionyl and Sulphuryl Amides, Imides, and Hydrazides (660); § 55. Nitrosulphinic and Nitrilosulphonic Acids and their Salts (666); § 56. Hydronitrilomonosulphonic Acid and its Salts (669); § 57. Nitrilohydroxydisulphonic Acid and its Salts (672); § 58. Nitrilotrisulphonic Acid and its Salts (680); § 59. Hydrazinosulphinic and Hydrazinosulphonic Acids (682); § 60. Peroxyamidodisulphonic Acid and its Salts (684); § 61. Hyponitritosulphuric Acid and its Salts (687); § 62. Nitratosulphuric Acid and its Salts (691); § 63. Nitrosylsulphonic Acid, and Hydroxynitrosylsulphonic Acid (692); § 64. Nitroxylsulphonic Acid or Nitrosylsulphuric Acid (696); § 65. Nitrosyl and Nitroxyl Compounds of Pyrosulphuric Acid (702); § 66. Derivatives of Amido-phosphorous and Amido-phosphoric Acids (704); § 67. Derivatives of Imido-phosphoric Acid (708); § 68. The Amidodiphosphoric or Amidopyrophosphoric

Acids (709); § 69. Imidodiphosphoric or Imidopyrophosphoric Acid (712); § 70. Amides and Imides of the Higher Phosphoric Acids (714); § 71. The Metaphosphimic Acids and their Salts (716); § 72. Phosphorus Chloronitrides or Phosphonitrilic Chlorides (721); § 73. Ammonia Derivatives of Thiophosphoric Acid (725).

CHAPTER L

PHOSPHORUS

§ 1. The History of Phosphorus (729); § 2. The Occurrence of Phosphorus (732); § 3. The Preparation of Phosphorus (740); § 4. The Allotropic Forms of Phosphorus (744); § 5. The Physical Properties of Phosphorus (754); § 6. The Oxidation of Phosphorus (771); § 7. The Chemical Properties of Phosphorus (782); § 8. The Atomic Weight and Valency of Phosphorus (799); § 9. Hydrogen Tritaphosphide, or Phosphorus Trihydride, or Phosphine (802); § 10. The Phosphonium Compounds (822); § 11. The Lower Hydrogen Phosphides (828); § 12. The Metal Phosphides (833); § 13. The Lower Oxides of Phosphorus (866); § 14. Hypophosphorous Acid (870); § 15. The Hypophosphites (879); § 16. Phosphorus Trioxide, or Phosphorous Oxide (891); § 17. Phosphorous Acid (899); § 18. The Phosphites (911); § 19. Metaphosphorous and Pyrophosphorous Acids and their Salts (921); § 20. Phosphorus Tetroxide or Phosphorosic Oxide (922); § 21. Hypophosphoric Acid (924); § 22. The Hypophosphates (931); § 23. Phosphorus Pentoxide, or Phosphoric Oxide (940); § 24. Orthophosphoric Acid (947); § 25. Pyrophosphoric Acid (971); § 26. Metaphosphoric Acid (977); § 27. The Polymetaphosphoric Acids and their Salts (984); § 28. Polyphosphoric Acids (990); § 29. Perphosphoric Acids (992); § 30. Phosphorus Fluorides (993); § 31. Phosphorus Dichloride and Trichloride (998); § 32. Phosphorus Pentachloride or Phosphoric Chloride (1009); § 33. The Oxychlorides of Phosphorus (1019); § 34. The Phosphorus Bromides and Oxybromides (1030); § 35. The Phosphorus Iodides and Oxyiodides (1037); § 36. The Mixed Halides and Oxyhalides of Phosphorus (1042); § 37. The Phosphorus Sulphides (1047); § 38. Matches (1058); § 39. Phosphorus Oxysulphides; the Thiophosphoric Acids and their Salts (1061); § 40. Phosphorus Sulphates (1071); § 41. Thiophosphoryl Halides, and Phosphorus Thiohalides (1071).

INDEX 1081

ABBREVIATIONS

aq. = aqueous
atm. = atmospheric or atmosphere(s)
at. vol. = atomic volume(s)
at. wt. = atomic weight(s)
T° or °K = absolute degrees of temperature
b.p. = boiling point(s)
θ° = centigrade degrees of temperature
coeff. = coefficient
conc. = concentrated or concentration
dil. = dilute
eq. = equivalent(s)
f.p. = freezing point(s)
m.p. = melting point(s)
mol(s) $= \begin{cases}\text{gram-molecule(s)}\\ \text{gram-molecular}\end{cases}$
mol(s). $= \begin{cases}\text{molecule(s)}\\ \text{molecular}\end{cases}$
mol. ht. = molecular heat(s)
mol. vol. = molecular volume(s)
mol. wt. = molecular weight(s)
press. = pressure(s)
sat. = saturated
soln. = solution(s)
sp. gr. = specific gravity (gravities)
sp. ht. = specific heat(s)
sp. vol. = specific volume(s)
temp. = temperature(s)
vap. = vapour

In the **cross references** the first number in clarendon type is the number of the volume ; the second number refers to the chapter; and the succeeding number refers to the "§," section. Thus **5**. 38, 24 refers to § 24, chapter 38, volume 5.

The oxides, hydrides, halides, sulphides, sulphates, carbonates, nitrates, and phosphates are considered with the basic elements ; the other compounds are taken in connection with the acidic element. The double or complex salts in connection with a given element include those associated with elements previously discussed. The carbides, silicides, titanides, phosphides, arsenides, etc., are considered in connection with carbon, silicon, titanium, etc. The intermetallic compounds of a given element include those associated with elements previously considered.

The use of **triangular diagrams** for representing the properties of three-component systems was suggested by G. G. Stokes (*Proc. Roy. Soc.*, **49**. 174, 1891). The method was immediately taken up in many directions and it has proved of great value. With practice it becomes as useful for representing the properties of ternary mixtures as squared paper is for binary mixtures. The principle of triangular diagrams is based on the fact that in an equilateral triangle the sum of the perpendicular distances of any point from the three sides is a constant. Given any three substances *A*, *B*, and *C*, the composition of any possible combination of these can be represented by a point in or on the triangle. The apices of the triangle represent the single components *A*, *B*, and *C*, the sides of the triangle represent binary mixtures of *A* and *B*, *B* and *C*, or *C* and *A*; and points within the triangle ternary mixture. The compositions of the mixtures can be represented in percentages, or referred to unity, 10, etc. In Fig. 1, pure *A* will be represented by a point at the apex marked *A*. If 100 be the

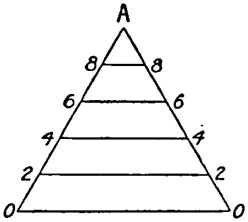

Fig. 1.

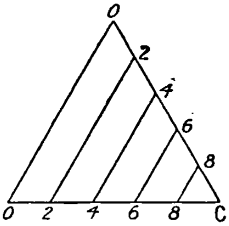

Fig. 2.

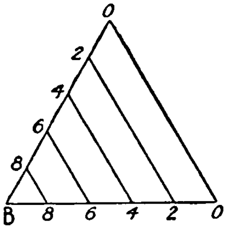

Fig. 3.

standard of reference, the point *A* represents 100 per cent. of *A* and nothing else; mixtures containing 80 per cent. of *A* are represented by a point on the line 88, 60 per cent. of *A* by a point on the line 66, etc. Similarly with *B* and *C*—Figs. 3 and 2 respectively. Combine Figs. 1, 2, and 3 into one diagram by superposition, and Fig. 4 results. Any point in this

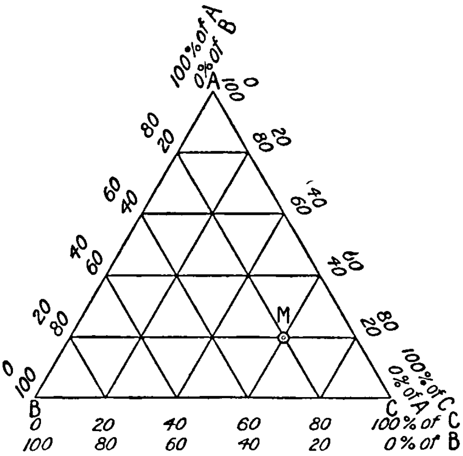

Fig. 4.—Standard Reference. Triangle.

diagram, Fig. 4, thus represents a ternary mixture. For instance, the point *M* represents a mixture containing 20 per cent. of *A*, 20 per cent. of *B*, and 60 per cent. of *C*.

CHAPTER XLIX

NITROGEN

§ 1. The Composition of the Atmosphere

> There are, I believe, few maxims in philosophy that have laid firmer hold upon the mind than that air, meaning atmospherical air (free from various foreign matters, which were always supposed to be dissolved, and intermixed with it), is a simple elementary substance, indestructible and unalterable, at least as much so as water is supposed to be.—J. PRIESTLEY.
>
> The air contributes to so great a number of chemical phenomena, by the combinations which it forms, that it is important to have a precise idea of the parts which compose it, and of the proportions in which its elements are found.—C. L. BERTHOLLET.

THE view of the ancient Greek philosophers in regarding air as one member of their quaternary system of elements; the history of the recognition of gases; the discovery that air has weight and exerts a pressure; and the discovery that air contains two dominant elements—oxygen and nitrogen—have been all discussed in the first volume of this work. M. E. Chevreul[1] wrote *sur les manières diverses dont l'air a envisagé dans ses relations avec la composition des corps*. In the eighteenth century, the evaporation of water into the atmosphere, and the condensation of water from the atmosphere, seem to have been an adequate proof of the mutual convertibility of air and water. This hypothesis was advocated by J. B. van Helmont, and it has been previously described (**1.** 3, 7). R. Boyle inclined to the same belief. Isaac Newton said that " heat converts water into vapour which is a kind of air "; and J. F. de Machy, and J. T. Eller held similar ideas. J. A. de Luc also said that electricity converts water vapour into common air, and this again into water; and he added that only in this way is it possible to explain the formation of clouds.

In a letter to R. Boyle[2] in 1678, Isaac Newton supposed that atmospheres of æther surrounded the particles of bodies which produce *cohesion*, varying with the distances, at great distances; and repulsion, at smaller distances; and added:

> The particles of vapour, exhalations, and air do stand at a distance from one another, and recede from one another as the pressure of the incumbent atmosphere will let them; for I conceive the confused mass of vapours, air, and exhalations which we call the atmosphere, to be nothing else but the particles of all sorts of bodies of which the earth consists, separated from one another and kept at a distance by the said principle.

In the seventeenth century, Robert Boyle also said:

> The air is a confused aggregate of effluviums from such differing bodies, that, though they all agree in constituting by their minuteness and various motions one great mass of matter, yet perhaps there is scarcely a more heterogeneous body in the world.

These words forcibly impress the fact that air is a mixture of several different gases—oxygen and nitrogen along with much smaller quantities of ammonia, and other nitrogen compounds; hydrogen; hydrocarbons; hydrogen dioxide; carbon dioxide; sulphur compounds; organic matter; chlorides; ozone; water vapour; and the noble or inert gases—argon, helium, krypton, neon, and xenon. The more carefully the composition of the atmosphere is examined, the more do we realize the application of Boyle's words.

Suspended solids in the form of **dust** are also common in air; thus, the outside air in London contains from 80,000 to 116,000 particles per c.c., while inside a room as many as 2,000,000 per c.c. have been counted. The air over the Pacific Ocean has been reported to have 280 to 2200 per c.c. The dust content of the atmosphere has been examined by H. H. Kimball and I. F. Hand, etc. A portion of the dust appears to be of meteoric or extra-terrestrial origin. A. E. Nordenskjöld,[3] and G. Tissandier found a dark brown dust on snow, etc., and it contained constituents like nickel, iron, phosphides, etc. A. von Lasaulx found no free iron in some dust collected at Catania; but he did observe the presence of quartz, mica, felspar, magnetite, augite, and diatoms. G. Tissandier found silica, calcium carbonate, alumina, iron chlorides and sulphates, and ammonium nitrate in atmospheric dust collected on snow. For two or three years after the eruption of Krakatoa in 1883; after the eruption of Mount Pelée and Santa Maria in 1902; and after the eruption of Katmai in 1912, a reddish-brown corona was sometimes observed as if it were around the sun. The phenomenon, known as *Bishop's ring*, was produced by the diffraction of sunlight by particles of volcanic dust in the upper regions of the atmosphere. The phenomenon was discussed by J. M. Pernter, and W. J. Humphreys. According to J. Aitken, dust of cosmic or terrestrial origin furnishes nuclei about which drops of rain are formed (**1.** 9, 6). F. O. Anderegg and K. B. McEachron showed that the fog formed when air containing ozone is passed through an absorbent soln., is chiefly caused by hygroscopic nitrogen pentoxide. According to J. J. Nolan:

> The chief evil of a polluted atmosphere is not the æsthetic horror of the smoke canopy, the grimy buildings and the stunted vegetation. It is not even the inspiration of dirty air—even though in the course of twenty-four hours of a heavy smoke fog, the dweller in London breathes in 500,000,000,000 particles of suspended matter. The real crime is the cutting off of sunlight.

The dust which is carried down with rain, hail, or snow has been analyzed by many. W. Stark, A. F. Wiegmand, W. L. Zimmermann, R. Brandes, C. Bertels, J. D. Bohlig, etc., noted the presence of calcium salts—chiefly sulphate—in rain-water; J. Girardin, in hail-stones; and A. F. Wiegmand, in snow-water. The last-named also noted the presence of phosphates in atm. dust—*vide infra,* chlorides, etc. A. Ditte, and W. N. Hartley and H. Ramage have discussed the occurrence of metals as well as meteoric dusts in the atmosphere.

Various kinds of **micro-organisms,** spores, etc., abound in the lower strata of the atmosphere. These may cause putrefactions, fermentations, and pathological phenomena of great hygienic importance. In 1744, G. Berkeley said:

> Nothing ferments, vegetates, or putrefies without air, which operates with all the virtues of the bodies included in it. The air, therefore, is an active mass of numberless different principles, the great sources of corruption, and generation; on the one hand, dividing, abrading, and carrying off the particles of bodies—that is, corrupting or dissolving them—on the other, producing new ones into being, destroying and bestowing forms without intermission. The seeds of things seem to be latent in the air, ready to pair and produce their kind whenever they light on a proper matrix. The extremely small seeds of ferns, mosses, mushrooms, and some other plants are concealed and wafted along in the air, every part whereof seems replete with seeds of one kind or other. The whole atmosphere seems alive. There is everywhere acid to corrode, and seed to engender.

The purification of air from matters in suspension has been discussed by L. Pasteur, J. Tyndall, E. T. Chapman, P. Miquel, W. Spring, F. Schulz, etc. Air may be freed from dust particles, etc., in suspension by filtration through biscuit earthenware, asbestos, or cotton wool. When a beam of sunlight is passed through unfiltered air, it reveals a multitude of motes constantly in motion. Lucretius, in his *De natura rerum* (**2.** 113, 60 B.C.), has given a very vivid description of the phenomenon. With filtered air, there is no such effect, and J. Tyndall said that such air is *optically empty.* F. O. Rice showed that in a number of reactions—*e.g.* the oxidation of soln. of sodium arsenite or sulphite, the decomposition of hydrogen dioxide, etc.—the suspended dust in air acts as a catalytic agent.

The oxygen-nitrogen ratio.—Some of the early workers believed that the proportion of oxygen and nitrogen in air varied with respect to place and time, as well as with the state of the weather. The analyses of C. W. Scheele,[4] A. L. Lavoisier, H. Cavendish, J. Dalton, J. L. Gay Lussac and F. H. A. von Humboldt, H. Davy, J. Priestley, and N. T. de Saussure rendered it highly probable that no sensible difference is to be found in the proportions of these two elements in air collected in different localities, and this is confirmed by analyses conducted more rigorously, with all known refinements. As C. L. Berthollet recognized in 1803, it appears that the variations reported by the early chemists were solely due to the uncertain action of the absorbents employed for removing oxygen from a mixture of that gas with nitrogen—*vide* the preparation of nitrogen.

In order to obtain a thorough knowledge of a great number of phenomena, said C. L. Berthollet,[5] it is important to ascertain, with all precision that can be attained, what are the proportions of oxygen and nitrogen which enter into the composition of the atm. A. Leduc calculated the composition of air from the sp. gr. of oxygen and nitrogen referred to air unity. Air may be analyzed gravimetrically or volumetrically. Historically, volumetric methods were developed before the gravimetric. In the gravimetric processes, the dried air freed from carbon dioxide is passed over hot copper (J. B. A. Dumas and J. B. J. D. Boussingault), or heated reduced iron (C. Brunner). The gravimetric analysis of air was made by C.Brunner in 1833. N. Laskowsky, and B. Verver, in 1843, weighed the oxygen absorbed by dry phosphorus, and measured the vol. of the nitrogen. J. B. A. Dumas and J. B. J. D. Boussingault absorbed the oxygen by heated copper, weighed before and after the absorption; the nitrogen was collected and weighed. They found that the ratio of the amount of oxygen in air is to that of the nitrogen as 3·682 : 12·373, that is as 22·92 : 77·08. As a mean of six determinations they obtained 23·005 grms. of oxygen per 76·996 grms. of nitrogen. The gravimetric process is very exact. The error need not exceed 0·00001th part of the whole; but the experiment requires special apparatus, and occupies much time. A similar method was used by J. S. Stas, J. C. G. de Marignac, B. Lewy, H. St. C. Deville and L. Grandeau, etc.

In volumetric processes, the oxygen is usually removed from the nitrogen by absorbents which should not disengage any gas, and which should have no action on the residual nitrogen. F. Fontana, 1774, and M. Landriani, 1775, investigated the subject, and the latter first applied the term *eudiometer* to the instrument devised by the former. J. Priestley, and C. W. Scheele, almost simultaneously, determined the quantitative composition of air, but the latter, in 1778, first attempted a systematic study of the composition of air over extended periods of time. He absorbed the oxygen by exposing a confined vol. of air to a mixture of iron filings with half its weight of powdered sulphur; he found this mixture to be more satisfactory than a soln. of potassium sulphide or calcium polysulphide later employed by A. de Marti, L. B. G. de Morveau, J. F. Berger, A. Henderson, J. L. Gay Lussac, F. C. Achard, J. de Fontanelle, J. Dalton, and M. P. Moyle. In J. Priestley's method of analysis, nitric oxide was gradually added to a measured vol. of air, in the presence of alkali-lye; the nitrogen peroxide formed by the union of nitric oxide and oxygen was absorbed by the liquid. The residual nitrogen was measured. This method of analysis was used a great deal about the beginning of the nineteenth century. Thus, F. Fontana, M. Landriani, J. H. de Magellan, J. Dalton, A. L. Lavoisier, N. T. de Saussure, J. A. Wanklyn and E. T. Cooper, J. Ingenhousz, J. G. S. von Breda, J. A. Scherer, D. A. Kreider, A. de Marti, F. H. A. von Humboldt, etc., employed this method; and H. Cavendish is said to have made over 500 analyses by this method before 1790. A. Seguin, and J. F. Berger discussed the errors of the method. D. A. Kreider passed a mixture of air and nitric oxide through a soln. of hydriodic acid, and determined, by titration, the iodine liberated. L. W. Winkler, and G. W. Chlopin determined the oxygen by treating air with manganous oxide in the presence of a soln. of potassium iodide, and determined the iodine by titration.

H. Davy, and W. Allen and W. H. Pepys employed a soln. of ferrous sulphate sat. with nitric oxide. A. Dupasquier removed the oxygen by shaking a confined vol. of air with freshly precipitated ferrous or manganous hydroxide; L. L. de Koninck, C. Brunner, and W. Flight, ferrous hydroxide; C. W. Scheele, finely divided iron, etc.; N. T. de Saussure, finely divided lead, or copper turnings moistened with sulphuric or hydrochloric acid; N. T. de Saussure, lead-waste; M. Rosenfeld, burning plumbiferous tin-foil; W. Bolton, aluminium amalgam; E. Ebermayer, A. T. Kupffer, H. A. von Vogel, L. Spallanzani, G. A. Giobert, J. B. Biot, H. E. Watson, P. Configliachi, J. F. Berger, G. F. Parrot, C. L. Berthollet, A. L. Lavoisier, A. de Marti, F. C. Achard, A. Seguin, J. J. Berzelius, A. von Baumgartner, A. Magnus-Levy, F. A. C. Gren, F. Laulanie, W. Hempel, and A. Leduc, phosphorus; S. Dumoulin, J. B. J. D. Boussingault, E. Turner, and A. F. E. Degen passed the air admixed with hydrogen over spongy platinum; and W. R. Grove found an electrically heated wire acted as well as spongy platinum. J. von Liebig, J. Schiel, C. Speck, R. A. Smith, F. G. Benedict, W. O. Atwater and F. G. Benedict, I. Macagno, J. S. Haldane, A. Krogh, A. Pécoul, A. Jaquet, H. Reboul, R. Stähelin, A. Gigon, A. Durig and N. Zuntz, K. Sondén, F. C. Calvert, S. Cloez, J. B. J. D. Boussingault, W. Hempel, and B. Tacke, absorbed the oxygen by shaking the air with an alkaline soln. of pyrogallol; soln. of tannic and gallic acids were also found to be good oxygen absorbents. An ammoniacal soln. of cuprous chloride has been tried by C. W. Scheele, D. R. T. Munoz de Luna, T. Schlösing, and M. P. L. M. Doyere, as an oxygen absorber; and a hydrochloric acid soln. of chromous chloride, by F. O. von der Pfordten, H. Moissan, N. H. Hartshorne and J. F. Spencer, R. P. Anderson and J. Riffe, W. Manchot and J. Herzog, and W. Hempel. L. G. de St. Martin, and O. Pettersson and A. Högland employed a soln. of sodium hyposulphite for absorbing oxygen—*vide* also the work of C. Brunner, and N. Dumoulin.

The methods employed by A. L. Lavoisier are only rough approximations. W. Hempel's method, with an absorption pipette, charged with sticks of phosphorus, gives very fair results. The air is first measured in a burette, then transferred to the pipette where the oxygen is absorbed, and transferred back to the burette for re-measurement. If the absorption pipette be charged with a soln. of pyrogallol in alkali-lye, the alkaline soln. becomes dark brown, almost black, as oxygen is absorbed. The explosion process may also be employed. This was devised by A. Volta in 1774, and tested by H. Cavendish in 1784. The method can give very accurate results. It was used by R. Bunsen, P. von Jolly, R. F. Marchand, W. Henry, J. F. Berger, A. R. Leeds, S. F. Hermbstädt, W. J. Russell, R. D. Thomson, C. W. Hinman, J. Dalton, H. V. Regnault and J. A. Reiset, E. Frankland and W. J. Ward, E. W. Morley, J. Geppert, A. Muntz and E. Aubin, T. Schlösing, M. Schaternikoff and J. Setschenoff, A. F. Samojloff and A. Judin, etc.

Analyses by J. S. Stas, J. C. G. de Marignac, B. Lewy, J. J. Berzelius, C. Brunner, A. Muntz and E. Aubin, M. Breslauer, B. Verver, R. Bunsen, and H. V. Regnault showed, as the last-named expressed it, that the oxygen and nitrogen in atm. air in temperate climes is approximately constant because the oxygen content was found to vary only between 20·9 and 21·0 per cent.; but in hot countries, the proportion of oxygen may fall as low as 20·3 per cent. On the other hand, P. von Jolly, E. W. Morley, A. R. Leeds, and I. Macagno believed that deviations larger than that observed by H. V. Regnault occurred. Thus, P. von Jolly found variations between 20·477 and 21·01 per cent. of oxygen in the air of München; and A. R. Leeds, between 20·821 and 21·029 in the air of New York. W. Hempel confirmed H. V. Regnault's conclusion; and U. Kreusler suggested that the incomplete desiccation of the gas in P. von Jolly's experiments explained his discrepant results. A. Krogh gave 20·948 per cent. of oxygen; 79·022, of nitrogen; and 0·030, of carbon dioxide. A small selection from the observed data is shown in Table I. The amount of atm. nitrogen varies reciprocally with the oxygen. If oxygen be high, the nitrogen will be low, and conversely. Hence, after making due allowance for differences in the methods of analysis by different men, it is clear that the **relative proportions of nitrogen and oxygen in the air are almost, but not quite, constant.** W. Hempel could detect no fluctuation in the proportion of oxygen, and the meteorological state of the air, nor could E. Ebermayer find a smaller proportion of oxygen in the air in a forest, than in the open air. E. W. Morley found that severe depressions of temp., the so-called cold-waves, are connected with the descent of air from great elevations, and the proportion of oxygen then fell from 21·006 to 20·867 per cent. by vol. A. Stock and G. Ritter found a variation of 0·75 per cent. in the oxygen content of even rural air. R. A. Smith showed that in crowded rooms, theatres, stables, cowsheds, etc., there is a shortage of oxygen. M. P. Moyle also found that the air of some Cornish mines contained as little as 14·51 per cent. of oxygen; J. F. L. Hausmann, in one of the Harz mines found 13 per cent. of oxygen; and C. H. Brockmann, an average of 19·785 per cent. of oxygen in ventilated mines of the Upper Harz. The minimum content of oxygen in air for respiration and combustion was discussed by R. A. Smith, C. Speck, F. Clowes, etc.

TABLE I.—OXYGEN CONTENT OF AIR IN DIFFERENT LOCALITIES.

Locality.	Minimum.	Maximum.	Average.	Authority.
London	20·79	21·05	20·885	R. A. Smith
Glasgow	20·85	21·01	20·909	R. A. Smith
Paris	20·913	20·999	20·960	H. V. Regnault
Manchester	20·78	21·02	20·943	R. A. Smith
Scottish Hills	20·80	20·18	20·970	R. A. Smith
Heidelberg	20·84	20·97	20·924	R. Bunsen
Bonn	20·90	20·939	20·922	U. Kreusler
Dresden	20·877	20·971	20·930	W. Hempel
Cape Horn	20·72	20·97	20·864	A. Muntz and E. Aubin
Cleveland, Ohio	20·90	20·98	20·933	E. W. Morley
Boston	20·928	20·938	20·932	F. G. Benedict

The analyses of air are usually expressed in terms of the contained oxygen and nitrogen, where the nitrogen is estimated by difference. As indicated in connection with the inert gases, Lord Rayleigh and W. Ramsay showed that the assumed nitrogen is really a complex mixture of nitrogen, argon, etc. A. Leduc estimated from the sp. gr. of the constituent gases, that the proportions of oxygen, nitrogen, and argon in air are:

	Nitrogen.	Oxygen.	Argon.
Weight	75·5	23·2	1·3
Volume	78·06	21·0	0·94

The argon was shown by W. Ramsay and M. W. Travers to be itself a complex of five inert gases—*vide* **7**. 48, 2. Air contains the following percentage proportions of these gases:

	Volume.	Weight.
Argon	0·932	1·285
Neon	0·0015	0·001
Helium	0·0005	0·00007
Krypton	0·000005	0·000014
Xenon	0·0000006	0·0000025

At sea-level, the principal gases present in dry air are very nearly in the following percentage amounts by vol.:

N_2	O_2	A	CO_2	H_2	Ne	He	Kr	X
78·03	20·99	0·93	0·03	0·01	0·0015	$0·0_35$	$0·0_55$	$0·0_66$

The average proportion of water vapour at sea-level decreases in passing from the equator to the poles, so that each of the other constituents varies proportionally. J. Hann [6] gives for the average values:

	N_2	O_2	A	H_2O	CO_2
Equator	75·99	20·44	0·92	2·63	0·02
50° N.	77·32	20·80	0·94	0·92	0·02
70° N.	77·87	20·94	0·94	0·22	0·03

There is a little evidence indicating that in the upper strata of the atmosphere, the composition of the air is very different from that in the lower strata. Air taken at sea-level contains rather a higher proportion of oxygen than air at higher altitudes. A. Wegener suggested that in the outermost regions of the atmosphere, there is a gas which he called **coronium,** or *geo-coronium.* A. Wegener estimated that the mol. wt. of coronium is 0·4; that the gas has monatomic mols.; and that the air contains about 0·00058 per cent. This gas was stated by J. Winlock to furnish a well-defined green line, 1473, in the spectrum of the aurora borealis. The same spectral lines —1474 and 5308—were reported by R. Nasini and co-workers in the spectra of some volcanic gases; by J. N. Lockyer, C. A. Young, and W. W. Campbell in the sun's corona during a solar eclipse; and by G. D. Liveing and J. Dewar, in the spectrum of the more volatile gases of the air. The evidence is circumstantial. As S. Chapman and E. A. Milne have pointed out, coronium is not likely to be present in the upper strata because, on account of its low density, it would probably not be retained by the earth. Attempts to find such a gas have failed—**7.** 48, 1.

According to W. J. Humphreys, and E. Gold, the **humidity** of the air rapidly decreases with increasing elevation to a negligibly small value at about 10 kilom.; the temp. decreases uniformly at the rate of about 6° per kilom. from an average of 11° at sea-level to —55° at an elevation of 11 kilom.; and beyond that altitude, the temp. remains constant at —55°. The relative percentages of the several gases in the air—excepting water vapour—remain constant at altitudes below 11 kilom. because of vertical convection currents; while above that elevation, the temp. changes but little with ascent, and the several gases are distributed according to their mol. wts. The air not only becomes more and more rarefied with increasing altitude, but its composition materially changes so that the heavier elements predominate in the lower strata, and the lighter elements in the higher strata.

Let b denote the barometric reading in mm.; h, the altitude in metres; θ, the temp.; and α, the coeff. of thermal expansion, approximately $\frac{1}{273}$ at 0°; then, with ordinary logarithms,

$$h=18400\log\left(\frac{760}{b}\right)(1+\alpha\theta)\quad.\ .\ .\ .\ .\ .\ .\ .\quad(1)$$

This equation is applicable to altitudes in which the composition of the atmosphere is nearly constant. The region of the earth's atmosphere which is kept approximately of a constant composition extends up to the altitudes affected by vigorous vertical convection currents. This level extends to an elevation of 11 kilom., beyond this up to the greatest altitude yet reached by sounding balloons, and presumably beyond this, the temp. changes comparatively little with change of altitude. In this isothermal region there can be but little vertical movement of the atmosphere and the several gases can distribute themselves as if each alone were present. The simple equation, $dp=pdh/H$, will therefore apply for the isothermal region, when p represents the partial press. of the gas under consideration, dh the change in elevation, and H the vertical height of the given gas, or its height, assuming its density throughout to be the same as the initial level, necessary to produce a press. p. The effect of gravity is neglected because it is so very small. The integrated equation is more adapted for numerical computation in the form:

$$\log p=\log p_0\dot{-}\frac{0{\cdot}434295}{H}(h-h_0)\quad.\ .\ .\ .\ .\ .\ .\quad(2)$$

The value of H for each gas is given by the expression $H=799D_aT/273D$, where T denotes the absolute temp.; D_a, the density of dry air, and D, that of gas in question—both at the same press. and at 0°. The percentage distribution of the gases in the atm. at different altitudes, computed by W. J. Humphreys from equations (1) and (2), is indicated in Table II; and the results are shown graphically in Fig. 1. The results for press. and temp. are supported by observations at altitudes up to 30 kilom.; and for the composition by samples of air collected by A. Wigand from heights of 9 kilom. (6 miles). The values at higher altitudes have the general uncertainty of extrapolated values. The subject has been discussed by J. H. Jeans, G. D. Hinrichs, E. W. Morley, J. Hann, E. Gold, W. J. Humphreys, J. B. A. Dumas and J. B. J. D. Boussingault, J. F. Benzenberg, K. L. Bauer, F. A. Lindemann, G. D. Hinrichs, L. Vegard, A. Rateau, F. W. Aston, etc. According to S. Chapman and E. A. Milne, the presence of hydrogen in the upper reaches of the atm. is not conclusively proved, and they showed that if it be absent, the atmosphere above 150 kilometres is almost entirely helium.

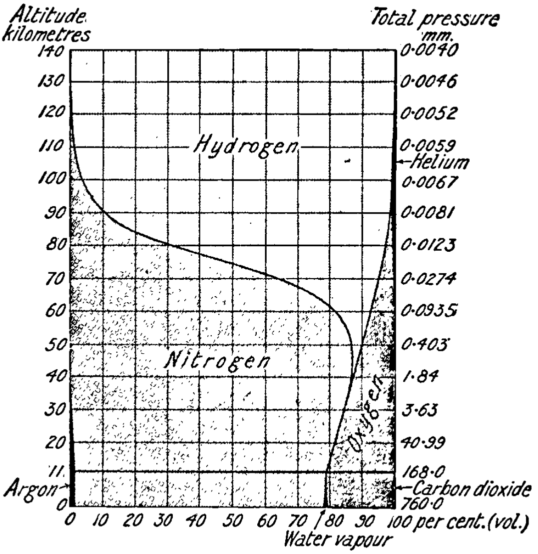

Fig. 1.—Diagrammatic Representation of the Composition of the Upper Atmosphere.

Table II.—Percentage Distribution of the Gases in the Atmosphere at Different Altitudes.

Carbon dioxide.—The existence of carbon dioxide in air was demonstrated by J. Black[7] between 1752 and 1754; ten years later by D. McBride; and in 1774, by T. Bergman. H. B. de Saussure employed lime-water as a test; and N. T. de Saussure, alkaline-lye. The latter process was used by A. F. de Fourcroy, F. H. A. von Humboldt, B. Lewy, E. Frankland, I. Macagno, etc., and P. Thénard weighed the barium carbonate produced by the action of the carbon dioxide on baryta-water.

Important memoirs were published by N. T. de Saussure, *Sur les variations de l'acide* *carbonique atmosphérique;* **J. B. A. Dumas,** *Sur l'acide carbonique normal de l'air atmosphérique ;* **W. Spring** and **L. Roland,** *Recherches sur les proportions d'acide carbonique contenues dans l'air ;* **A. Müntz** and **E. Aubin,** *Sur la proportion d'acide carbonique contenu dans l'air ;* **E. Wollny,** *Untersuchungen über den Kohlensäuregehalt der Bodenluft ;* and **E. A. Letts** and **R. F. Blake,** *The Carbonic Anhydride of the Atmosphere.*

Early reports gave remarkably high values for the proportion of carbon dioxide in atm. air. Thus, C. Girtanner gave 100–200 vols. per 10,000 vols. of air; F. A. H. von Humboldt, 50–180; J. Dalton, 6·83; and P. Thénard, 3·97. Later work reduced these figures, and in 1870, 4 vols. in 10,000 was considered to be the normal proportion in spite of the work of R. F. Marchand, who obtained 3·10; R. A. Smith, 3·36; T. E. Thorpe, and A. Krogh, 3·0; and F. Schulze, 2·86–3·01 vols. per 10,000. It was supposed that these figures were low owing to the proximity of the sea; but the determinations of J. A. Reiset, etc., indicate that the **proportion of carbon dioxide in the atmospheric air oscillates about 3 vols. in 10,000,** or, according to A. Müntz and E. Aubin, 2·82 in 10,000 for the northern hemisphere and 2·72 in 10,000 for the southern.

There is a slight increase in the proportion of carbon dioxide over *land surfaces* at night which is attributed by J. von Fodor, and E. Wollny not to the cessation of vegetable activity, but to the ground air which is normally rich in that gas. As night approaches, there is a fall of temp., and the ground air, which is then warmer than the atm., escapes and enriches the atm. with that gas. The evidence that vegetation, apart from ground air, reduces the proportion of carbon dioxide in the atm. is not very definite. The proportion of carbon dioxide in air is rather higher in towns than in the open country; but the agitation and diffusion of air by winds, etc., prevents an excessive accumulation in any part—excluding, of course, badly ventilated rooms. Thus, J. A. Reiset (1882) found 3·027 vols. of carbon dioxide per 10,000 vols. of air in Paris; and near Dieppe, 2·942 vols. These numbers may be regarded as normal. O. Haehhal found 0·4048 grm. of carbon dioxide per 100 litres of air in Berlin.

In towns, during a fog, 7 or 8 vols. of carbon dioxide in 10,000 vols. of air may accumulate; and in badly ventilated rooms, ten times the normal amount of carbon dioxide may be present. The proportion of carbon dioxide in the atm. increases during *fogs and mists;* the increase is slight in country districts, and very marked in thickly populated towns. There is generally a slight decrease in the proportion of carbon dioxide in the atm. when *rain* is falling, but there is a complication due to the effect of ground air. The general opinion is that there is an increase in atm. carbon dioxide when *snow* is falling; there is also an increase during frosty weather, and a decrease during a thaw. An increase of *wind* lessens the proportion of carbon dioxide owing to the agitation and consequent intermixture of the different air strata. At a given spot, however, the amount of carbon dioxide may vary with the nature of the surface over which the wind has previously traversed. If this happens to be water, there will probably be less carbon dioxide than with land which usually has rather more of that gas. A diminution of *pressure* should lead to an increase of carbon dioxide both over land and sea—in the former case by liberating gases from the soil, and in the latter by decomposing hydrocarbonates. A lowering of the *temperature* abates the velocity of diffusion of carbon dioxide from the lower to the upper strata of the atm.; and conversely when the temp. is raised. There are indications, more or less marked, of variations in the proportion of carbon dioxide with the *seasons.* The production and evolution of the gas from soil in early spring is checked in the summer months, and is followed in the later period of the year by an increase when vegetal activity has ceased. The effect of *clouds and sunshine* was discussed by J. A. Reiset, and A. Müntz and E. Aubin. According to W. J. Russell, the amount of carbon dioxide is below the average when the weather is fine with bright sunshine. In the country this is assumed to arise from an increase in vegetal activity, and in the city by a better circulation of air. The effect of altitude was discussed by H. B. de Saussure, N. T. de Saussure, H. and A. Schlagintweit, E. Frankland,

R. A. Smith, P. Truchot, G. Tissandier, A. Müntz and E. Aubin, E. A. Letts and R. F. Blake, E. Ebermayer, W. Marcet and A. Landriset, J. A. Reiset, and F. Schulze. Some of the earlier observers noted an increase in the proportion of carbon dioxide with moderate elevations; others, a decrease. Later observers have been unable to detect any distinct difference one way or another. For higher altitudes, *vide supra*, Fig. 1.

Attempts by C. E. Brown-Sequard and A. d'Arsonval,[8] and S. Merkel have been made to show that the depressed feeling and uneasiness experienced in crowded rooms is not solely due to the diminution of oxygen, and increase of carbon dioxide, but is rather due to the presence of a volatile organic poison in the expired air. This hypothesis was contested by A. Dastre and P. Loye, A. Russo-Giliberti and G. Alessi, D. H. Bergey, S. W. Mitchell and J. S. Billings, G. von Hofmann-Wellenhof, and K. B. Lehmann and F. Jessen. O. Wurster, and T. Cramer attributed the injurious effects to the presence of nitrates.

Moisture.—J. B. Porta[9] condensed moisture from the atmosphere on the walls of a glass vessel containing a freezing mixture. The average amount of moisture, aqueous vapour, in air is rather less than one per cent. by vol.; it may reach 4 per cent. in humid climes. The actual amount of aq. vapour air can carry before it is sat. depends upon the temp. The higher the temp. the greater the amount of moisture air can carry. Air is sat. with moisture when it contains all the water vap. it can retain at that temp. without condensation; if the air is partially sat., it will tend to become sat. by absorbing moisture. The heat required to vaporize the water may be supplied directly by the water being vaporized; or by objects in contact with the water. The variations in the proportion of water in the atmosphere are responsible for the phenomena classed as *weather*. The way it enters the atmosphere, the forms in which it is made visible, and the manner in which it is precipitated from the atmosphere, are discussed in books on meteorology. H. Kohler has discussed the form of the water drops in fogs, basing his observations on the coronæ of fogs and clouds. Even down to −28°, the drops in fogs are spherical drops, and are not crystalline.

The amount of moisture in milligrams per litre in air sat. with water vap. has been calculated by H. C. Dibbits from the vap. press. tables of G. Magnus, H. Ebert, and H. V. Regnault. The results by the latter are shown in Table III. Atm. air is never dry, and it is rarely sat. even during a heavy rain shower. According to J. H. Poynting, and G. N. Lewis, the quantity of moisture in sat. air depends both on the temp. and on the press. Air under press., in contact with liquid water, will take up more moisture at high than at low press. Air seldom contains less than 75 per cent. of the amount which it is capable of holding; but much depends on the local conditions—*e.g.*, in the Libyan desert the air contains but 9 per cent. of the possible amount of moisture.

TABLE III.—WEIGHT OF WATER IN SATURATED AIR FROM −20° TO 40° (MILLIGRAMS PER LITRE).

Temp. °C. × 10	0°	1	2	3	4	5	6	7	8	9
−2	1·058	—	—	—	—	—	—	—	—	—
−1	2·299	2·147	1·988	1·839	1·701	1·571	1·450	1·342	1·241	1·146
−0	4·868	4·527	4·201	3·898	3·617	3·355	3·112	2·886	2·676	2·481
0	4·868	5·209	5·570	5·953	6·359	6·789	7·246	7·730	8·242	8·784
1	9·356	9·961	10·600	11·275	11·987	12·788	13·531	14·366	15·246	16·172
2	17·147	18·173	19·252	20·386	21·578	22·830	24·144	25·524	26·971	28·488
3	30·079	31·746	33·492	35·320	37·232	39·232	41·324	43·511	45·797	48·185
4	50·677	—	—	—	—	—	—	—	—	—

The **absolute humidity** of air refers to the mass of water vapour actually present in unit vol., and it is determined by passing a known vol. of air over a suitable drying agent—calcium chloride, phosphorus pentoxide, etc. (**1.** 7, 2)—and finding the increase in the weight of the desiccating agent. The results can be expressed in milligrams per litre, grams per cubic metre, etc. The absolute humidity is also expressed in terms of the press. exerted by the water vapour per unit area—dynes per sq. cm., millimetres of mercury, etc.—since the press. exerted by any component in a uniform mixture of gases is to the total press., as the number of its mols. per given vol. is to the total number of mols. in the mixture. Hence, the vap. press. varies directly as the vapour density, or mass per unit vol. The two definitions of absolute humidity are therefore eq. for any assigned temp. The term **specific humidity,** occasionally used, refers to the weight of water vapour in unit weight of moist air. The term **relative humidity,** at any given temp., refers either to the ratio of the actual to the saturation quantity of water vapour per unit vol.; or to the ratio of the actual to the saturation press. of water vapour. The **dew-point** is the temp. at which without change of press., the air is saturated; it is the temp. at which the saturation press. is the same as the existing vap. press. of the water. If θ_s° be the dew-point, when the saturation or maximum vap. press. is f_s; and the vap. press. at θ is f; the relative humidity is f/f_s. Again, let p mm. denote the barometric press.; θ°, the temp.; and f, the vap. press.; then, if θ° be the temp. of a well-ventilated wet-bulb thermometer, and f_s the saturation vap. press. at θ_1°, then, with temp. expressed in °C, and press. in mm. of mercury, the vap. press. f, at θ°, is given by the empirical formula $f=f_s-0{\cdot}000660p(1+0{\cdot}00115\theta_1)(\theta-\theta_1)$. Hence, when f is known, the relative humidity can be calculated. According to J. Dalton's law, $P=p+f$, where P represents the observed barometric press.; p, the corresponding press. of dry air; and f, the press. of the water vapour. This law is applicable when the air is sat.; if the air be not sat., then if h denotes the relative humidity (per cent.), $P=p+hf$.

Ozone and hydrogen dioxide.—Probably these substances are formed by electrical discharges in the atm. as indicated in connection with the formation of these substances (**1.** 14, 2 and 8). There is probably sufficient ozone in the earth's atm. to be of importance with both the incoming and the outgoing radiation. The magnitude of solar energy consumed by ozone is uncertain because the amount of this gas in the air is also unknown. Ozone in moist air at ordinary temp. soon reverts to oxygen so that only traces of it are found in the lower atmosphere. On the contrary, in the upper atmosphere where there is but little moisture, and where the temp. approximates to −55°, ozone is far more stable; the extreme ultra-violet rays emitted by the sun, when passed into cold dry oxygen, convert much of it into ozone so that, according to H. Henriet and M. Bonyssy,[10] and W. J. Humphreys, appreciable amounts of this gas are presumably present in the upper atmosphere. J. N. Pring estimates the ozone in the upper atmosphere to be eq. to a layer of pure gas 4·2 cms. thick, at normal temp. and press. The upper atmosphere is relatively richer in ozone than air from lower levels. E. Ladenburg and E. Lehmann have measured the absorption spectrum of ozone down to $\lambda=12\mu$; A. K. Angström discovered solar bands $\lambda=4{\cdot}7\mu$ and $\lambda=9{\cdot}5\mu$ respectively, and the observed limit of the solar spectrum appears to be fixed by an ozone band of extraordinary absorptive power whose maximum occurs at about $\lambda=0{\cdot}254\mu$—*vide* Fig. 2. H. N. Holmes found the proportion of ozone in atm. air to be greater in winter than in summer.

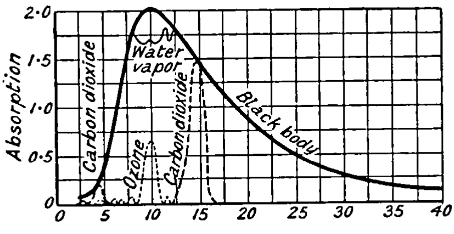

FIG. 2.—Water vapour, carbon dioxide, and ozone absorption at 14·2°.

Hydrogen and combustible carbon compounds.—The occurrence of hydrogen in atm. air is derived from the sources indicated in connection with that gas—*vide* the occurrence of hydrogen. G. D. Liveing and J. Dewar [11] found hydrogen in distilling liquid air. Lord Rayleigh estimated that one vol. of hydrogen is present in 30,000 vols. of air. G. Claude found less than one part of hydrogen in a million parts of air. N. T. de Saussure found hydrocarbons in atm. air, and this was confirmed by J. B. J. D. Boussingault. B. Verver found that the air of Lyons contained one vol. of hydrocarbon in 10,000 vols of air. W. Omeliansky made some observations on the occurrence of methane in air. A. Müntz and E. Aubin reported the presence of methane, carbon monoxide, etc., in atm. air; and A. Müntz found traces of alcohol in the air, and in rain-water. F. C. Phillips could detect no hydrogen in atm. air; but A. Gautier found that the air in the neighbourhood of towns contains variable quantities of combustible carbon compounds, but only minute traces of these gases can be detected in the air of mountainous regions, and in sea-air. For instance, the air of Paris contains per 100 litres—19·4 c.c. of free hydrogen, 12·1 c.c. of methane, 1·7 c.c. of benzene and related hydrocarbons, and 0·2 c.c. of carbon monoxide with traces of olefines and acetylenes. A. Leduc, and Lord Rayleigh considered that A. Gautier's estimate for hydrogen is probably rather high. H. Henriet found 2 to 6 grms. of formaldehyde per 100 cubic metres of air. The presence of hydrocarbons explains the oleaginous character of the deposits which form on roofs, leaves of trees, etc., in towns. W. L. Zimmermann and others have reported on various forms of organic matter in atm. air, or in rain-, hail-, or snow-water. According to A. Gautier, the hydrogen in the atm. may be derived, not only from volcanic action and other well-known sources, but also from the action of water on ancient granitic rocks at temp. considerably below a red-heat. Granite from the interior of a fairly large block, powdered in an atm. of carbon dioxide and afterwards heated with dil. acids at 100° or with water alone at 280°, yields a considerable quantity of gas, consisting mainly of hydrogen, together with hydrogen sulphide, ammonia, carbon dioxide, nitrogen, and traces of unsaturated hydrocarbons, and sometimes traces of methane. The hydrogen and the ammonia are probably due to the action of water on nitrides, chiefly iron nitrides, although possibly some of the hydrogen may be derived from its action on carbides.

Chlorine and iodine compounds.—Rain near the sea brings down a certain amount of chloride derived from the sea-water. The proportion of salt in the air is greatest near the sea-shore, and diminishes rapidly inland from the coast. In 1822, J. C. Driessen wrote a memoir: *De acidi muriatici præsentia in aëro atmosphærico.* Observations on the occurrence of hydrochloric acid or rather chlorides in the atmosphere were made by A. Vogel,[12] M. Roubaudi, W. Meissner, J. von Liebig, and W. A. Lampadius. J. Dalton found that at Manchester, 10,000 kgrms. of rain-water contain more than a kilogram of sodium chloride. R. A. Smith made observations on the chlorides in air in the vicinity of Manchester. R. Brandes obtained 312 kgrms. of solid matter from a million kilograms of rain-water, and found that the residue contained potassium, sodium, manganese, iron, calcium, ammonium, and magnesium chlorides, carbonates, and sulphates, and organic matters. J. I. Pierre stated that at Caen, a hectare of land receives annually by rain sodium chloride, 37·5 krgms.; potassium chloride, 8·2 kgrms.; magnesium chloride, 2·5 kgrms.; and calcium chloride, 1·8 kgrms. J. A. Barral estimated that every hectare at Paris receives the eq. of 13 kgrms. of chlorine by rain annually; and E. Kinch found, as an average of twenty-six years' observations at Cirencester, that 36·1 lbs. of sodium chloride per acre per annum were brought to the earth with the rain. The amount of "wind-borne" sea salt is greatest when the wind blows from the sea. Observations were also made by G. Bellucci, G. C. Whipple and D. D. Jackson, A. Bobierre, E. L. Peck, N. H. J. Miller, J. Pirovaroff, J. B. Harrison and J. Williams, G. Gray, E. S. Richards and A. T. Hopkins, B. Artis, J. de Fontenelle, N. Passerini, J. B. Lawes and co-workers, and A. Gautier. Numerous other observations have been made from the agricultural point of view in studying the saline substances carried to the soil from the atm. by rain. F. W. Clarke has compiled Table IV showing the amount of chlorides precipitated on land by rain. The results are expressed in pounds per acre per annum.

TABLE IV.—CHLORIDES BROUGHT TO THE SURFACE OF THE EARTH BY RAIN.

British Guiana	129·24	195·00
New Zealand	61·20	—

According to A. Gautier, at 15°, a quantity of chlorine eq. to 0·022 grm. of sodium chloride per cubic metre of air represents the maximum quantity of salt which sea air can retain in suspension. In 1877, F. Posepny, and E. Tietze discussed the atmospheric circulation of salt, and tried to show that the sodium chloride of inland waters is derived from this source. W. Ackroyd, and A. Müntz advocate this view, and, added the latter, without this circulation of salt, the land would not be replenished, and living beings would suffer. E. Dubois estimated that about 6,000,000 kgrms. of salt are annually precipitated by rainfall on two provinces of Holland. These *cyclic salts*, or wind-borne salts, play a distinct part in the economy of nature. R. A. Smith showed that free hydrochloric acid derived from manufacturing operations is sometimes found in air of towns. A. Gautier found that less than 0·002 mgrm. of free iodine, or gas containing iodine, is present in about 4000 litres of dust-free air of Paris; similarly, the dust-free air from the sea, forest, or mountain districts contains no appreciable quantity of iodine. No iodine in the form of soluble salts is present in the small particles of dust in the air. The air from Paris and from the sea contain respectively 0·0013 mgrm. and 0·0167 mgrm. of iodine in 1000 litres. This iodine is probably present in small vegetable organisms suspended in the air. It is detected by filtering the air through glass wool, and afterwards fusing the latter with potash. Although the presence of iodine as a normal constituent of the atmosphere was denied by F. Garrigou, S. Cloez, and S. de Luca, its presence was confirmed by E. Marchand, A. Chatin, A. A. B. Bussy, P. Thénard, and J. Bouis—*vide* **2.** 17, 5.

Nitrogen oxides.—In the eighteenth century, B. Ramazzini,[13] A. S. Marggraf, and T. Bergman observed that snow-water contains some vestiges of nitric acid—*vide infra*, nitric acid. As shown by F. Goppelsröder, E. Bechi, R. A. Smith, and G. Defren, the oxides of nitrogen are probably formed by electrical discharges in the atmosphere. The nitrites or nitrates obtained from atm. air are greater during thunderstorms than during ordinary rain. J. von Liebig, indeed, said that only the rain of a thunderstorm contains nitric acid, but other observers agree that nitric acid or nitrates occur more frequently. Thus, G. Defren found that water exposed undisturbed to the air absorbs nitrites there existing; and the amount so absorbed increases in almost direct proportion to the time of exposure. Free nitric acid has been reported in the atm. of tropical regions, but generally, the nitric acid is combined with ammonia. J. A. Barral estimated that 63·6 kgrms. of nitric acid fall per hectare per annum at Paris; and A. Bineau observed at Lyons 0·3 mgrm. of nitric acid per litre of rain in winter; 1·0 mgrm. in spring; 2 mgrms. in summer; and 1·0 mgrm. in autumn. According to A. Lévy, about 3 lbs. of ammoniacal nitrogen, and 1 lb. of nitric acid is returned to the earth per acre per annum with the rain. In rural districts the soil is said to receive between 4 and 6 lbs. of combined nitrogen per acre per annum from the rain. Observations on the presence of nitric acid or nitrates were also made by W. Knop, J. B. J. D. Boussingault, W. A. Lampadius, J. F. Heller, R. A. Smith, C. F. Mabery and H. Snyder,

F. Goppelsröder, A. Bobierre, E. Bechi, C. Chabrier, A. Müntz and V. Marcano, R. Warington, J. B. Harrison and J. Williams, J. B. Lawes and co-workers, etc. Table V was compiled by F. W. Clarke—*vide infra*—where the data are expressed in pounds per acre per annum. The occurrence of nitrous acid in air and rain was discussed by G. Chabrier, F. Goppelsröder, and L. I. de Nagy Ilosva. According to W. Hayhurst and J. N. Pring, the proportion of nitrous acid in atm. air varies from time to time, being less than 1 part in 4,000,000,000 parts of air; the proportion is greater at high than at low altitudes. The ratio of the oxides of nitrogen in the upper to that in the lower atmosphere was found to be 2·23 : 1 at 8500 ft. elevation, and 1·76 : 1 at 2600 ft. elevation.

Ammonia.—In the eighteenth century, C. W. Scheele[14] noted that the mouths of bottles containing acids were encrusted with ammonium salts after standing in a room for some time; and J. B. A. Chevallier found that ammonium salts—carbonate, nitrate, nitrite, sulphide, and acetate—were present in the air of Paris. Other observations were made by N. T. de Saussure, T. Bergman, R. Brandes, J. von Liebig, J. I. Pierre, A. Schöyen, W. L. Zimmermann, C. S. Collard de Martigny, E. N. Horsford, C. R. Fresenius, G. Ville, B. Artis, E. L. Peck, P. Truchot, N. Gräger, H. T. Brown, F. Goppelsröder, A. Lévy, G. Kemp, J. A. Wanklyn, W. Knop, E. Bechi, A. Schlösing, A. Müntz and co-workers, H. T. Brown, J. B. Lawes and co-workers, J. B. Harrison and J. Williams, and R. Warington. According to M. Faraday, if china clay be heated to redness and exposed to air for a week, it yields a considerable quantity of ammonia when heated again, which is not the case when the clay has been kept in a closed vessel. The ammonia in the atmosphere is largely a product of organic decomposition, and it is returned to the earth by rain in the form of ammonium nitrate or nitrite, and sometimes as ammonium sulphate or chloride. Numerous observations have been made on the amount of ammonia present in atm. air, and carried down by rain-water. J. A. Barral estimated that every hectare at Paris receives annually 15·3 kgrms. of ammonia, and A. Bineau, at Lyons, 68 kgrms. J. B. J. D. Boussingault observed that the most ammonia is present in the first part of a rainfall. After some days without rain, he observed successively the following proportions of ammonia per litre:

Rain gauge	0·5	0·5–1	1–5	5–10	10–15	15–20	20–31 mm.
Ammonia	3·11	1·20	0·70	0·45	0·45	0·41	0·40 mgrms.

The proportion condensed during fogs is greater, reaching in one case 50 mgrms. of ammonia per litre. Falling snow contains a notable proportion of ammonia; the snow collected on a terrace contained 1·78 mgrms. per litre, and that collected on an adjoining garden, 10·34 mgrms. per litre. This is taken to mean that ammonia was set free from the soil and intercepted and absorbed by the snow. A. Bineau obtained 70 mgrms. per litre by the melting of a hoar frost. R. A. Smith found in

England 0·97 mgrm. per litre of rain in the country, and 5·14 mgrms. in the towns; and in Scotland, 0·53 mgrm. in the country, and 3·81 mgrms. in the town. Table V shows that ammoniacal nitrogen is usually in excess of nitric nitrogen, but the converse is true of tropical countries. The ammonia is usually collected by the acids—nitric, hydrochloric, or sulphuric—in the atmosphere and carried to earth in rain or snow.

Sulphur compounds.—Sulphuric acid and sulphates found in rain-water may be derived in part from water which is volatilized from seas, lakes, and rivers, being carried mechanically along with the vapour; or it may be formed in the air itself—*vide* sulphuric acid. Thus, G. F. Rouelle,[15] about the middle of the eighteenth century, said:

> When one steeps a well-cleaned cloth in potash-lye free from sulphuric acid, and exposes it to the air in a place free from rain and dust, the cloth becomes wet and dry alternately a great many times; at last it becomes dry and does not again become wet; the potash with which it was impregnated, is found changed into sulphate.

P. von Driessen and M. Veehof found sulphuric acid; and F. d'Arcet, and J. B. A. Chevallier, sulphur dioxide and sulphuric acid in the air of towns, and it was supposed to have been derived from the combustion of coal. R. Brandes, and J. de Fontenelle observed the presence of sulphates in the solid residue formed by the evaporation of rain-water. Alkali sulphates in contact with organic matter may be reduced to hydrogen sulphide; the same gas can be produced by the putrefaction of organic matter; and it occurs among the gases given off by volcanoes. Sulphur dioxide is emitted by volcanoes, and is produced by the combustion of coal. Hence, this gas (*q.v.*) is to be expected in the air of manufacturing districts. Thus, A. Ladureau reported 1·8 c.c. of sulphur dioxide per cubic metre in the air of Lille; and O. Haehhal found 0·003281 grm. of SO_2 per 100 litres of air in Berlin. Sulphur compounds are present in small quantities as hydrogen sulphide, sulphur dioxide, and sulphuric acid in the air of towns. The rapid oxidation of sulphur dioxide in the presence of moisture results in the formation of sulphuric acid or of the sulphates. According to R. Warington, about 17¼ lbs. of sulphuric acid are annually "poured" upon each acre of land at Rothamsted. G. H. Bailey reported a maximum of 0·0267 grm. of sulphur estimated as sulphur trioxide in the air near the surface of the ground in Manchester. J. I. Pierre showed that in the vicinity of Caen, a hectare of land receives annually by rain, sodium sulphate, 8·4 kgrms.; potassium sulphate, 8·0 kgrms.; calcium sulphate, 6·2 kgrms.; and magnesium sulphate, 5·9 kgrms. Other observations have been made by J. B. Lawes and co-workers, S. Robinet, R. A. Smith, N. H. J. Miller, G. Gray, B. Artis, and E. L. Peck.

Is air a mixture or a compound of oxygen and nitrogen?—Observations by P. A. Guye and co-workers,[16] W. J. Humphreys, E. W. Morley, etc., have shown that there is probably a very small conc. of the denser gas, oxygen, in the atm. near the surface of the earth—*vide supra*—although analyses of air collected from mountain tops, and balloons have not borne out this suspicion. The fact that the proportions of oxygen and nitrogen in air do not vary with moderate variations of altitude appears to have been mainly responsible for the belief that these gases are in a state of chemical combination. C. L. Berthollet, T. Thomson, J. Murray, and H. Davy at first "leaned towards the idea of chemical combination," and J. Gough added that if the particles of oxygen exist in the atm. independently of the particles of nitrogen, sound will be transmitted by the one gas with one velocity, and by the other gas with another velocity, so that at a sufficient distance away a sound should be heard double. The view that air is a chemical compound was persistently maintained until the advent of J. Dalton's theorems in 1801 explaining the relation of mixed gases towards one another. J. Dalton showed that "when two elastic fluids, denoted by A and B, are mixed together, there is no mutual repulsion amongst their particles, that is, the particles of A do not repel those of B, as they do one another." In the proof, it was shown that if two kinds of air are put into the same vessel with very great care, without the least agitation that might mix or blend them together, each gas diffuses uniformly throughout the other. A light gas cannot rest long on a heavier gas. Particles of one kind may offer a kind of passive resistance to the motion of the particles of the other kind, and act as temporary obstacles in the same way as the pebbles in a stream impede the flow of water (1. 4, 4). The following summarizes the main evidence :

1. The proportions of the constituents of air vary a little in different localities, but even this small variation is not found with pure chemical compounds—law of constant proportions. Hence, not all the nitrogen and oxygen are combined.

2. The atomic proportion of nitrogen and oxygen in air is as 3·77 : 1 ; this is approximately as 15 : 4. Hence, if all the nitrogen and oxygen are combined, the formula of the compound is $N_{15}O_4$, or $NO_{0·26}$, which does not fit very well with the facts summarized by the law of multiple proportions. A similar result is obtained by considering the volume-temperature relations of nitrogen and oxygen in air.

3. The characteristic physical properties (refractive index, absorption of radiant heat, etc.) of nitrogen and oxygen are modified in air only so far as obtains when nitrogen and oxygen are *mixed* in the same proportions. The properties of the two gases are not changed so much as would be expected if a chemical compound were formed. Thus, J. B. Biot found that the refractive index of air is equal to that calculated for an eq. mixture of oxygen and nitrogen ; and J. Tyndall found that the amount of heat absorbed when heat rays are allowed to pass through a column of an elementary gas is much less than is the case with compounds. Thus, air, oxygen, nitrogen, and hydrogen have nearly the same value—say unity—whereas carbon monoxide has an absorptive power of 972 ; nitric oxide, 1590 ; nitrous oxide, 1860 ; and ammonia, 5460. According to H. St. C. Deville, if a measurable physical property were different in air and in an equivalent mixture of the constituents of air, the conclusion would follow that air is a compound.

4. The constituents of air can be separated by mechanical means, *e.g.* solution in water : by atmolysis ; by allowing liquid air to vaporize, when the nitrogen distils off before the oxygen ; and J. Dewar showed that liquefied air like liquid oxygen will remain suspended to a magnet in virtue of the oxygen it contains ; there is no separation. If, however, the liquid air be solidified, the oxygen can be separated from the nitrogen by means of an electromagnet much as iron filings can be separated from brass turnings. Hence, solid air behaves like a magma whose constituents, nitrogen and oxygen, can be separated by a magnet.

5. No heat, no change of vol., or any other sign of chemical change is observed when air is made artificially by mixing the gases together in the correct proportions.

Not one of these five reasons is in itself conclusive, but all, taken together, form a long chain of circumstantial evidence which quite justifies J. W. Dobereiner's verdict : *Das atmosphärische Gase ist keine chemische Verbindungen.* Air is a mechanical mixture of nitrogen, oxygen, etc.

§ 2. The Physical Properties of Air

Some observations on the weight of air were made at the beginning of the fourth chapter—**1**. 3, 1—of this work. J. B. Biot and F. J. Arago[1] said that the **weight of a litre** of dry air, freed from carbon dioxide, and at 0° and 760 mm., is 1·299541 grm. ; and J. B. A. Dumas and J. B. J. D. Boussingault gave 1·2995 grm. Later workers obtained rather smaller values—thus, H. V. Regnault gave 1·293187 grm. ; J. M. Crafts, 1·29349 ; P. von Jolly, 1·29383 ; M. S. Blanchard, 1·29287 ; G. Agamennone, 1·29310 ; W. Lasch, 1·293204 ; F. Kohlrausch, 1·293635 ; A. Leduc, 1·2933 ; Lord Rayleigh, 1·29327 ; and P. A. Guye, 1·2930. O. J. Broch, and J. Treuthardt made some observations on this subject. The best representative value for the weight of a litre of dry air, freed from carbon dioxide, at 0° and 760 mm., is 1·2930 grm., at sea level, and latitude 45°.

According to A. Leduc, the weight of a litre of air can vary by a milligram owing to variations in composition. There is therefore no particular advantage in weighing air to a greater accuracy than $\frac{1}{20}$th of a milligram without at the same time determining the composition of the air. For the same reason, there is no need to measure the density of other gases with respect to air to an accuracy greater than 0·0001. Accepting A. Leduc's value 0·08985 grm. for the weight of a litre of hydrogen, the **relative density** of air, referred to hydrogen unity, is 14·394 : and with Lord Rayleigh's value, 0·09001 grm. for the weight of a litre of hydrogen, the relative density of air is 14·368. W. Lasch made some observations on this subject. G. P. Baxter discussed the determination of the density of air. M. Paya and E. Moles found the normal density of the nitrogen from the air of Madrid is 1·25681 ; and the density of the air indicates a slightly higher proportion of oxygen, which is attributed to the presence of a higher proportion of ozone and argon gases than normal. A. Stock and G. Ritter found a variation of 0·13 per cent. on the density of even rural air. E. Moles added that since the normal density of air may vary as much as 0·1 per cent., the use of air as a standard for gas densities should be abandoned. A. Jaquerod and C. Borel found that the amplitude of the variations in the density of the air of Neuchâtel does not usually exceed 0·5–0·6 mgrm. The same result was found with air taken at an elevation of 2000–5000 m., but the deviation is smaller. The explanation which assumes the presence of a heavy gas is rejected and the presence of ultramicroscopic dust is suggested. Water at 4° is 773 times as heavy as a litre of air at 0° and 760 mm. The **specific gravity** of air referred to that of water is 0·0012933 with A. Leduc's data, and 0·0012932 with Lord Rayleigh's. P. A. Guye gave 0·0012928 for the best representative value ; values given by A. Leduc, Lord Rayleigh, P. A. Guye and co-workers, and F. O. Germann range from 0·0012973 to 0·0012926. The results in Table VI for the sp. gr. of dry air, with 0·04 vol. per cent. of carbon dioxide, at 760 mm., were calculated from $D=0{\cdot}00129307/(1+a\theta)$, where the constant $a=0{\cdot}0036730$ from 0°

to 50°; 0·0036715 from 0° to 100°; 0·0036704 from 0° to 150°; and 0·0036696 from 0° to 200°. A. Rateau discussed the effect of altitude on the sp. gr. of air.

S. von Wroblewsky measured the sp. gr. of liquid air. U. Behn and U. Kiebitz gave for the sp. gr. of liquid air referred to water at 4°:

	−195·7°	−195°	−193°	−191°	−189°	−187°	−185°	−183°	−182·4°.
D .	0·701	0·826	0·919	0·995	1·050	1·092	1·118	1·130	1·131

A. Ladenburg and C. Krügel showed that the composition quickly changes as the liquid is exposed to the atm., and the sp. gr. changes in a corresponding way. Newly condensed air with 53·83 per cent. of oxygen had a sp. gr. 0·9951; after standing some time, it had 64·2 per cent. of oxygen, and a sp. gr. 1·029; and after standing between one and two days, it contained 93·6 per cent. of oxygen, and had a sp. gr. 1·112. Liquid air with the same composition as atm. air has a sp. gr. 0·87 to 0·90. The sp. gr., D, of liquid air at its b.p., and containing x per cent. of oxygen, is represented by $D=0·86+0·00289x$. J. K. H. Inglis and J. E. Coates found that liquid air, with y vol. per cent. of nitrogen, at 74·70° K., and a vap. press. of 100 mm. of mercury, has the following vol., v:

y .	0	1·8	13·9	37·8	59·3	86·8	98·8	100
v .	0·28332	0·28429	0·27959	0·28301	0·28200	0·28324	0·28065	0·28214

According to J. Natterer,[2] the **compressibility** of atm. air does not deviate very markedly from Boyle's law, and L. Cailletet showed that only at very high press.—up to 2790 atm.—is air a little more compressed than corresponds with that law. H. V. Regnault found the ratio p_0v_0/pv, increased from 1·001414 with $p_0=738·7$

mm. and $p=1476{\cdot}3$ mm., to 1·006619 with $p_0=11472{\cdot}0$ mm. and $p=20969{\cdot}4$ mm. P. Siljeström said that with increasing dilution, the elasticity of air is greater than that which corresponds to Boyle's law. D. I. Mendeléeff inferred that Boyle's law is equally valid for air at low and at high press.; and that as the press. is diminished air deviates more and more from the law, thus, if $pv=1$ at 650 mm. press., $pv=0{\cdot}6$ at 0·5 mm. press. V. Hemilian and co-workers found a greater compressibility than corresponds with Boyle's law for air at press. over 760 mm., and conversely for press. between 20 mm. and 650 mm. On the other hand, E. H. Amagat found that air follows Boyle's law very closely for press. between 0·001 mm. and 10·5 mm. of mercury; at 100°, air follows Boyle's law between 1 and 8 atm. press. and probably for higher press. For unit vol. of air at 1 atm. press. and 15°, he found:

p .	750	1000	1500	2000	2500	3000 atm.
v .	0·002200	0·001974	0·001709	0·001566	0·001469	0·001401

He inferred accordingly that at high press., the coeff. of compressibility of air is of the same order of magnitude as that of a liquid. The press. in atm. at which the product pv is a minimum for different temp. was found by E. H. Amagat to be:

TABLE VII.—E. H. AMAGAT'S VALUES FOR pv FOR AIR.

p Atm.	0·0°		15·70°		99·40°		200·4°

p . .	75	139	162	151	125	104	c. 14 atm.

He calculated the compressibility coeff., $\beta=dv/vdp$ to be $0{\cdot}0_3411$ between 750–1000 atm.; $0{\cdot}0_3268$, between 1000–1500 atm.; $0{\cdot}0_3167$, between 1500–2000 atm.; $0{\cdot}0_3123$ between 2000–2500 atm.; and $0{\cdot}0_493$ between 2500–3000 atm. Observations were also made by F. M. Penning, A. W. Witkowsky, P. Koch, and M. W. Travers. L. Holborn and J. Otto gave $pv=1{\cdot}73317+0{\cdot}72317p+1{\cdot}8167p^2$ at 200°; $pv=1{\cdot}36713+0{\cdot}20933p+3{\cdot}1000p^2$ at 100°; and $pv=1{\cdot}00080-0{\cdot}79333p+5{\cdot}2222p^2$ at 0°. V. Fischer, W. J. Walker, P. Weiss, and E. Fouché discussed the **equation of state** of nitrogen.

O. E. Meyer[3] and numerous others have measured the **viscosity** of atm. air.

The values at 0° range from $\eta=0{\cdot}0_31679$ to $0{\cdot}0_31880$; at 20° from $\eta=0{\cdot}0_31780$ to $0{\cdot}0_31980$:

	−191·4°	−145°	−115°	−82°	−38°	0°
η . .	$0{\cdot}0_4579$	$0{\cdot}0_4240$	$0{\cdot}0_4590$	$0{\cdot}0_31060$	$0{\cdot}0_31570$	$0{\cdot}0_31880$

The following data for temp. up to 100° are by O. Schumann, for 197·3° by A. von Obermayer, for 302° by P. Breitenbach; and for the remaining temp., by W. J. Fisher:

	0°	40°	80°	100°	197·3°	302·3°	501·2°
η .	$0{\cdot}0_31679$	$0{\cdot}0_31896$	$0{\cdot}0_32153$	$0{\cdot}0_32290$	$0{\cdot}0_32538$	$0{\cdot}0_32993$	$0{\cdot}0_33606$

R. A. Millikan gave for the best representative value at 23°, $\eta=0{\cdot}0001824$; and for temp., $\theta°$, between 12° and 30°, $\eta=0{\cdot}0_318240-0{\cdot}0_6493(23-\theta)$. E. L. Harrington gave 0·00018226 at 23°, and K. S. van Dyke, 0·00018221. Numerous formulæ have been proposed. W. Sutherland gave $\eta=\eta_0 1{\cdot}414145(1+0{\cdot}003665\theta)\frac{1}{2}(1+113T^{-1})-1$; O. E. Meyer, $\eta=\eta_0(1+0{\cdot}003665\theta)0{\cdot}760$; and S. W. Holman found that at $\theta°$, the viscosity $\eta=0{\cdot}00017155(1+0{\cdot}002751\theta-0{\cdot}0000000034\theta^2)$. J. H. Jeans gave $\eta=\eta_0(T/273)^{0{\cdot}76}$. F. A. Williams also studied the effect of temp. on the viscosity of air. L. Gilchrist showed that the presence of unsaturated water vapour in the air has no measurable effect on the viscosity at normal press. and 20°.

Dew-point . .	6·6°	11·6°	14·1°	17°	Saturated
$\eta\times10^7$ . .	1·810	1·816	1·811	1·807	1·816

Although the average value for unsaturated air is about 0·3 per cent. less than for saturated air, G. Zemplén obtained a greater difference, *viz.*, 0·8 per cent., and W. Crookes found that the presence of water vapour did not affect the coeff. of viscosity of air until the total press. was less than half the normal press., and for lower press. the viscosity diminishes, but not so much as is required by formulæ based on the kinetic theory of mixed gases. J. C. Stearns discussed this subject. K. Przibram described a demonstration experiment. S. Ray obtained a negative result for the effect of a transverse electric field on the viscosity of air. F. Kleint measured the viscosities of various mixtures of oxygen and nitrogen gases; and P. Breitenbach, of mixtures of ethylene and air. J. E. Verschaffelt and co-workers measured the viscosity of liquid air and of various mixtures of oxygen and atm. nitrogen, and found at −193·53°, $\eta=0{\cdot}001599$ with 9·5 per cent. oxygen; 0·001678 with 35 per cent. oxygen; 0·001865 with 61 per cent. oxygen; and 0·001895 with 91 per cent. oxygen. S. Chapman and E. A. Milne discussed the rapid increase in the effective kinematical viscosity of air at great heights owing to the decrease in density.

According to L. Grunmach,[4] the **surface tension** of liquid air at −190·3° containing 49·9 vol. per cent. of oxygen is 11·61 dynes per cm.; and the **specific cohesion,** 2·406 sq. mm. and liquid air with 65·3, 67·6, and 76·45 vol. per cent. of oxygen has the respective surface tension 12·05, 11·91, and 12·51 dynes per cm., and for the values of the sp. cohesion, 2·376, 2·312, and 2·376 sq. mm. The **diffusion** coeff. of carbon dioxide and air at 0° was found by J. Loschmidt to be 0·142 sq. cm. per sec., and by K. Waitz, 0·136; A. von Obermayer gave for air and oxygen, 0·178 at 0°; J. Stefan, for air and carbon disulphide, 0·0995 at 0°; F. A. Schulze, for air and hydrogen, 0·661 at 17°; F. Houdaille, air and steam, 0·203 at 0°; and G. Guglielmo, air and steam 0·239 at 8°, and 0·248 at 18°. A. Winkelmann reported observations on this subject. T. Graham measured the rate of diffusion of air through porous plugs. C. Barus discussed the slow diffusion of air in water. J. Dewar found that air, at atm. press. and 15°, diffused through rubber 0·01 mm. thick at the rate of 2·0 c.c. per sq. cm. per day. L. Dufour, and E. Reusch observed that dry air diffuses more rapidly than moist air through a porous septum, and through hydrophane. J. Sameshima and K. Fukaya studied the atmolysis of air. Measurements of the **velocity of sound** in air at 0° range from M. Frot's [5] 330·7 metres per second to G. Moll and A. van Beek's 332·77 metres per second. F. Himstedt and R. Widder found the ratio of the velocities of sound in air at 20° and at —78·73° to be 0·8147. The relation of the velocity to the sp. ht. was discussed by A. Leduc. S. R. Cook observed 216·73 metres per second at —150·0°, and 253·75 metres per second at —106·2°. E. H. Stevens found for the velocity, V, in metres per second:

	0°	100°	300°	500°	750°	1000°
V . .	331·32	386·5	478·1	552·8	632·0	700·3

Observations were also made by H. B. Dixon and co-workers. N. de Kolossowsky studied the relation between the velocity of sound and the speed of translation of the molecules.

Observations on the dimensions of the constituent molecules were made by A. O. Rankine,[6] E. Dorn, W. Sutherland, W. Altberg, C. Ramsauer, and P. Lenard. The mean **velocity** of the molecules, at 0° and 760 mm. press., is given as 44,690 cm. per second; the mean **free path,** $0{\cdot}0_5608$ cm.; and the **molecular diameter,** $0{\cdot}0_731$ cm. K. S. van Dyke, and E. Blankenstein discussed the coeff. of slip, and of momentum transfer in air; and D. Brunt, the kinetic energy of the atmosphere.

E. H. Amagat[7] found the coeff. of **thermal expansion** to be 0·00367 for dry air, and 0·00368 to 0·00369 for moist air; P. von Jolly gave 0·00366957; and D. I. Mendeléeff and N. Kajander, 0·003684 at atm. press. A. Cazin found the coeff. of expansion at 5 atm. to be the same as at 1 atm. press. H. Teudt obtained an abnormally high expansion between 350° and 500°, and attributed the results to mol. dissociation. This, however, has not been confirmed by other workers. A. Jaquerod and F. L. Perrot gave 0·0036643 between 0° and 1066°. According to E. H. Amagat, the value of α at constant press., p atm., at different temp. is:

	0° to 15·7°			0° to 99·4°			99·4° to 200·4°		
p .	200	1000	3000	100	500	1000	200	500	1000
α .	0·00475	0·00206	0·00110	0·00444	0·00331	0·00314	0·00287	0·00241	0·00171

and at constant press., the values of the coeff. β are:

	0° to 15·7°			0° to 99·4°			99·4° to 200·4°		
p .	100	1000	2400	100	300	500	100	200	400
β .	0·00446	0·00567	0·00403	0·00462	0·00600	0·00617	0·00319	0·00351	0·00360

Observations were also made by L. Holborn and H. Schultze; and A. W. Witkowsky found for 0° to 100° at 10 atm. α=0·00375, and from 0° to 16°, 0·00376. At 30 atm. press., at temp. ranging from 0° to θ°:

θ	100°	16°	—78·5°	—130·5°	—140°	—145°
α	0·00392	0·00398	0·00420	0·00434	0·00492	0·00519

and from 0° to 100°, at p atm. press.:

p . .	10	30	50	70	90	110	120
α . . .	0·00375	0·00392	0·00410	0·00425	0·00437	0·00445	0·00449

R. Mewes discussed the deviations from Charles' law.

Measurements of the **thermal conductivity** of air at 0° range from P. A. Eckerlein's[8] 0·00004677 to W. Schwarze's 0·00005690. L. Graetz gave $0{\cdot}0_44838$ at 0° and $0{\cdot}0_45734$ at 100°; A. Schleiermacher's values are $0{\cdot}0_4562$ at 0° and $0{\cdot}0_47197$ at 100°. P. A. Eckerlein gave $0{\cdot}0_43678$ at —59° and $0{\cdot}0_42146$ at —149·5°. Observations were also made by D. J. Janssen, A. Winkelmann, P. Compan, A. Kundt and E. Warburg, E. Müller, and H. Gregory and C. T. Archer, who gave $K=0{\cdot}0000583(1+0{\cdot}000297\theta)$; E. Schneider gave $0{\cdot}0002477(1+0{\cdot}0039\theta)$; and S. Weber, $0{\cdot}0002379(1+0{\cdot}00365\theta)$. H. Gregory and C. T. Archer found that by varying the press. from 760 mm. to 360 mm., the thermal conductivity of air was not changed; but on further decreasing the press., a decrease in conductivity became apparent, but did not amount to more than a few per cent. until the press.

fell below 1 mm., when the conductivity began to fall off rapidly. E. O. Hercus and T. H. Laby studied this subject.

F. de la Roche and J. E. Bérard[9] gave for the **specific heat** of air at constant press. c_p=0·2669 from 0° to 100°; H. V. Regnault, 0·238 between 30° and 10°; 0·237 between 0° and 100°, and 0·237 between 0° and 200°; W. F. G. Swann gave 0·2414 at 20°, and 0·2430 at 100°; and K. Scheel and W. Heuse, 0·2409 at 20°, 0·2433 at −76°, and 0·2500 at −181°; E. Wiedemann, c_p=0·2389; R. Thomas, 0·2345 at 17° to 35°; R. Oehme, 0·2371 at 20°; H. N. Mercer, 0·2403; A. Eggert, 0·2372 at 0°; and W. Escher, 0·2376 at 50°. F. Keutel gave C_v=4·90 for the mol. heat of air at one atm. press., at 0°, and between 0° and 1000°, C_v=4·90+0·000436. R. Thibaut gave C_p=7·075 at 350°; and K. Scheel and W. Heuse, 6·965 at 20°. Observations were also made by F. Kohlrausch, L. Witte, A. Cazin, E. H. Amagat, E. Schreiner, A. Wüllner, V. Fischer, W. D. Wormesley, K. Nesselmann, and A. W. Witkowsky. According to L. Holborn and L. Austin, the effect of raising the temp. is to raise the sp. ht. of air, freed from carbon dioxide, thus:

	0°	100°	200°	400°	600°	800°	1000°	1200°	1400°
c_p .	0·2405	0·2415	0·2424	0·2443	0·2453	0·2481	0·2500	0·2519	0·2538

These results were represented by the formula $c_p=0{\cdot}2405+0{\cdot}0_5 95\theta$. W. D. Womersley gave for the sp. ht. at constant vol., c_p=0·2002 or C_v=5·803 between 0° and 1500°; and c_v=0·2056 or C_v=5·961 between 0° and 2000°. R. T. Glazebrook discussed these results. The observed values in the proximity of room temp. range from C_p=6·796 to 7·755; and C_v=4·801 to 5·742. H. B. Dixon and co-workers gave $C_v=4{\cdot}8+0{\cdot}0004T$. For the effect of press. on the sp. ht. of air at 20°–100°, L. Holborn and M. Jacob gave for p in kgrms. per sq. cm.:

p .	1	25	50	100	150	200	300
c_p .	0·2415	0·2490	0·2550	0·2690	0·2821	0·2925	0·3026
C_p .	6·991	7·209	7·394	7·788	8·167	8·468	8·760

For the ratio of the two sp. hts. at 0°, A. Leduc gave 1·404; E. Grüneisen and E. Merkel, 1·4034; J. R. Partington and co-workers, 1·4103 at 17°; H. N. Mercer, 1·400; W. C. Röntgen, 1·405 at 18°; H. W. Moody, 1·4011 at 20°; K. Schöler, 1·40 at 20° and 1 atm., or 1·41 at 20° and 3 atm. press.; A. Kalähne, 1·39 at 900°; O. Lummer and E. Pringsheim, 1·4025 at 5° to 14°; J. Jamin and F. Richard, 1·41; H. Kayser, 1·412 at 0°; P. A. Müller, 1·4046 at 16°; E. Paquet, 1·4038; J. W. Low, 1·3947; G. Maneuvrir, 1·395; W. Makower, 1·402; B. Hartmann, 1·413 at 12°; M. Guéritot, 1·403; M. C. Shields, 1·4029 at 20°; and T. C. Hebb, 1·4031 at 0°; K. Scheel and W. Heuse, 1·401 at 20°, 1·402 at −76°, and 1·448 at −181°; E. H. Stevens, 1·40 at 0° and 100°, and 1·34 at 950°; and W. Koch, at −79°, 1·40 at one atm. press., 2·20 at 100 atm. press., and 3·33 at 200 atm. press. The observed values in the proximity of room temp. range from 1·347 to 1·415. J. H. Brinkworth gave 1·4032 for the ratio at 17°, and 1·4154 at −118°. G. Piccardi studied the thermal capacity of air.

The **Joule-Thomson effect** for air was measured by J. P. Joule and W. T. Thomson,[10] J. P. Dalton, E. Vogel, F. Nöll, L. G. Hoxon, J. R. Roebuck, K. Olschewsky, F. G. Keyes, H. Hausen, N. Eumorfopoulus and J. Rai, and W. P. Bradley and C. F. Hale. Expressing the press. in kilograms per sq. cm., F. Nöll found the results indicated in Table VIII.

In 1732, H. Boerhaave[11] tried without success to condense air to the liquid state by artificial cold; and in 1850, J. Natterer likewise failed in an attempted **liquefaction** of air, although he compressed the gas under nearly 3000 atm. press.; but in 1877, L. Cailletet obtained liquid air in the form of a mist by compressing dried air, freed from carbon dioxide, at the temp. of liquid nitrous oxide, and under 200–225 atm. press., and suddenly releasing the press.; and in 1884, J. Dewar described a method of liquefying air cooled by means of liquid or solid nitrous oxide —*vide* 1. 13, 25. Various forms of apparatus have been devised for liquefying air

TABLE VIII.—JOULE-THOMSON EFFECT AT DIFFERENT TEMPERATURES AND PRESSURES.

Temp.	Pressure.				
	0	25	50	100	150
−55° . . .	0·44	0·40	0·37	0·28	0·18
−34° . . .	0·38	0·34	0·31	0·24	0·17
−0·6° . . .	0·27	0·25	0·24	0·19	0·16
49° . . .	0·20	0·18	0·17	0·15	0·12
100° . . .	0·14	0·13	0·13	0·10	0·08
150° . . .	0·09	0·09	0·07	0·06	0·05
199° . . .	0·05	0·04	0·04	0·04	0·03
250° . . .	0·02	0·02	0·02	0·01	0·01

and preserving the liquid, by J. Dewar, C. von Linde, K. Olschewsky, A. Stock and B. Hoffmann, R. Pictet, R. Mewes, G. Claude, F. G. Cottrell, W. P. Bradley and G. O. P. Fenwick, etc. Probably, L. Cailletet first solidified air in 1878; and in 1894, J. Dewar obtained it as a clear, transparent solid. The equilibrium relations in the liquefaction of air were studied by J. H. Simons.

For the **critical temperature** of air, K. Olschewsky[12] gave —140·0°, and for the **critical pressure,** 39·0 atm.; S. von Wroblewsky gave respectively —141·0° and 39·2 atm.; A. W. Witkowsky, 140·9°, and 39 atm.; and E. H. Amagat, —140·7° and 35·9 atm. The last-named gave 0·344 for the **critical density.** J. P. Kuenen and A. L. Clark gave for the critical temp., —140·63° to —140·53°; for the critical press., 37·17 to 37·27 atm.; and for the critical density, 0·31 to 0·35. S. F. Pickering gave for the best representative values T_c=132·4° K.; p_c=37·2 atm.; and D_c =0·33 grm. per c.c. S. von Wroblewsky gave —192·2° for the **boiling point** of liquid air, and K. Olschewsky, —191·4°. The latter also measured the **vapour pressure,** p atm., of liquid air at different temp. with the following results:

	−205°	−191·4°	−176°	−169°	160·5°	−152°	−146°	−142°	−140°
p . .	0	1	4·0	6·8	12·5	20·0	27·5	33·0	39·0

S. von Wroblewsky said that while in many of its properties atm. air behaves like a homogeneous gas, so that its critical constants have been determined, yet the liquefaction of air is accompanied by various complex phenomena, resembling those noticed in the compression of a mixture of five volumes of carbon dioxide with one of air. Thus, if atm. air is compressed until the meniscus first formed disappears, and the press. allowed to decrease slowly, there are produced two superposed menisci, separating heterogeneous fluids, in which the relative proportion of oxygen and nitrogen is different, the lower fluid containing about 21·3 per cent., and the upper 17·5–18·5 per cent. oxygen. Secondly, the vap. press. curves of atm. air are not regular, inasmuch as on compression the temp. at first sinks uniformly in proportion to decrease of press., until a minimum point at —198° is reached; on further compression the temp. begins to rise to a maximum at —196°, and thence decreases. These irregularities of the vap. press. curves show that the two constituents of the air are not vaporized equally, and the temp. observed is dependent on the momentary composition of the fluid. J. P. Kuenen and A. L. Clark studied the condensation phenomena in the critical region; they found the temp. and press. corresponding with the plait-point are —140·73° and 37·25 atm., and with the critical point of contact, —140·63° and 37·17 atm. The density of the liquid at these points is 0·35 and 0·31. The critical density of air calculated from the critical densities of oxygen and nitrogen by the simple mixture rule is 0·34.

The composition of liquid air in equilibrium with its vapour has been determined by E. C. C. Baly—*vide* Figs. 25 and 26, **1.** 13, 26. His values for absolute temp. of the boiling liquid and vapour with different mol. percentages of oxygen are:

O_2	0	10	20	40	60	80	90	100 mol. per cent.
$T_{\text{vap.}}$	77·54°	79·6°	81·3°	84·4°	87·0°	89·1°	90·0°	90·96°
$T_{\text{liq.}}$	77·54°	78·3°	78·8°	80·7°	83·1°	86·3°	88·4°	90·96°

J. K. H. Inglis determined the compositions of liquid and vapour in equilibrium with each other during the isothermal distillation of mixtures of liquid oxygen and nitrogen at $-74{\cdot}7°$, $-198{\cdot}3°$ and $-193{\cdot}93°$. If R_v and R_l are the respective ratios of nitrogen to oxygen in vapour and liquid, and m, the molar percentage of nitrogen in the liquid, then, at $-198{\cdot}3°$, $R_v/R_l=5{\cdot}48-0{\cdot}0207m$. When the total and partial press. of the oxygen and nitrogen are plotted, the curves have only a slight curvature. The results also show that the solubility of nitrogen in oxygen is in accord with Henry's law (**1.** 10, 4) up to a molar percentage of 70; after that, the variation of the quotient C/p for oxygen indicates an association of the oxygen mols. dissolved in the liquid nitrogen. The phenomena connected with the isothermal distillation or fractional condensation of liquid air have been discussed by A. Grusinoff, G. Claude, H. Erdmann, D. A. Goldhammer, K. T. Fischer and H. Alt, E. A. le Sueur, J. K. H. Inglis and J. E. Coates.

The **heat of evaporation** of liquid air was measured by T. Estreicher,[13] and U. Behn. According to J. S. Shearer, the heat of vaporization depends on the proportion of oxygen; and G. Witt represented the latent heat of vaporization of liquid air by $L=49{\cdot}59+0{\cdot}0143p$ cals., where p represents the percentage of oxygen in the mixture; the latent heat of vaporization of nitrogen is 49·59 cals., and of oxygen, 51·92.

Numerous observations [14] have been made on the **index of refraction** of dry atm. air for the D-line, and numbers ranging from $1{\cdot}0_32911$ of L. Lorenz to $1{\cdot}0_32947$ of E. Ketteler have been reported. H. Kayser and C. Runge gave the following data where the values of μ should have 1·000 . . . prefixed to them:

λ	0·759	0·687	0·656	0·589	0·527	0·486	0·431	0·397	0·393
μ	2905	2911	2914	2922	2933	2943	2962	2978	2980

λ	0·382	0·373	0·359	0·344	0·336	0·329	0·318	0·310	0·302	0
μ	2987	2993	3003	3015	3023	3031	3043	3053	3064	3

E. W. Cheney found $1{\cdot}0_32925$ for $\lambda=5852$ A.; $1{\cdot}0_32919$ for $\lambda=6143$ A.; and $1{\cdot}0_32912$ for $\lambda=6678$ A. A. Pérard found for the visible spectrum:

λ	0·4358	0·5461	0·5780	0·5986	0·6438μ
μ	$1{\cdot}0_329668$	$1{\cdot}0_329334$	$1{\cdot}0_329273$	$1{\cdot}0_329421$	$1{\cdot}0_329177$

The index of refraction is proportional to the press. at 600 mm. and 760 mm.; and it is related to temp., θ, by $\mu_0-1=(\mu-1)(\times 0{\cdot}003716\theta)$, where μ_0 is the index of refraction at 0°, and μ that at $\theta°$. V. Posejpal, and A. Mallock made some observations on the effect of press., p, on the sp. refraction of air, and found $\mu-1=0{\cdot}36269\times10^{-6}p(1+0{\cdot}0_5357p)$. W. Traub represented his results between $\lambda=0{\cdot}185\mu$ and $0{\cdot}546\mu$ by $(\mu-1)10^7=551716/(199{\cdot}5534-\lambda^{-2})-4880{\cdot}3/(43{\cdot}8193-\lambda^{-2})$; J. Koch gave $(\mu^2-1)10^8=57642+327{\cdot}7/(\lambda^2-0{\cdot}005685)$; and L. Lorenz, $\mu=\mu_0-0{\cdot}0_155f/(1+a\theta)$, when μ_0 represents the index of refraction of dry air at the same temp. and press., and f mm. denotes the partial press. of the mixture in the atmosphere; M. Opladen studied the effects of between 1 and 10 atm. press. G. D. Liveing and J. Dewar gave $\mu=1{\cdot}2062$ for the index of refraction of liquid air for the D-line. A. Zwetsch studied the effect of press. on the index of refraction of air. E. Stoll gave for the **dispersion of light** for $\lambda=4388$ to 9224 A., in air, $(\mu-1)10^7=2871{\cdot}87+16{\cdot}170\lambda^{-2}$, where λ is expressed in μ. Lord Rayleigh, and J. Cabannes and J. Granier studied the polarization and the scattering of light in air. G. I. Pokrowsky, and D. Banerji concluded that the scattering of light in the atmosphere is largely due to small particles of dust.

There are numerous phenomena produced in the atm. by foreign substances in suspension—*vide infra.* The subject is discussed by J. M. Pernter and F. M. Exner in their *Meteorologische Optik* (Berlin, 559, 1910), and W. J. Humphrey in his

Physics of the Air (Philadelphia, 426, 1920). The apparent magnification of the zenith distance of celestial objects is produced by the so-called astronomical refraction discussed by Lord Rayleigh,[15] A. R. McLeod, and others; the twinkling of stars was examined by L. Respighi. The **refraction of light** by a mass of water droplets suspended in air produces rainbows, etc.; the refraction of light by minute ice crystals of the cirrus and other clouds produces haloes of various kinds; the **diffraction of light** from cloud droplets produces commas, iridescent clouds, and the mountain-spectre or Brocken-spectre; and the scattering of light by the molecules of air produces the blue colour of the sky. The **polarization** of sky-light, discovered in 1811 by D. F. J. Arago, is produced by reflection from relatively large particles—cloud droplets, dust, etc.—and the combination of primarily and secondarily scattered radiation. This subject was discussed by Lord Rayleigh, C. Soret, etc. The **electromagnetic rotation of the plane of polarization,** ω, for light of wave-length, λ, between $0{\cdot}423\mu$ and $0{\cdot}684\mu$, at 13°, was represented by L. H. Siertsema[16] by $\omega = 0{\cdot}0001915\lambda^{-1} + 0{\cdot}00004619\lambda^{-3}$.

The **colour** of a cloudless sky is generally blue, but, according to circumstances, it may have the whole range of spectral tints. The zenith at great altitudes is distinctly violet, and at moderate altitudes blue; as the angular distance from the vertical increases the colour finally merges into a grey near the horizon. Just after sunset, or before sunrise, different parts of the sky may appear green, yellow, orange, or dark red, dependent on the humidity and dust content of the atmosphere. Attempts to explain the blue colour date from the sixteenth century, when Leonardo da Vinci suggested that the blue is a mixture of white light with that of black space. Isaac Newton[17] attributed the blue colour to a kind of interference between the rays reflected from the front and rear surfaces of minute transparent drops of water. R. Clausius showed that such droplets would cause the stars and celestial objects to appear much magnified; and he assumed that the droplets must be hollow. E. Brücke showed that the droplets are not hollow, and that the blue produced by the droplets of water is not the same as the blue of the sky. He further showed that a transparent medium containing a sufficient number of small particles appears blue when illuminated with white light; and that objects can be seen clearly and distinctly through such a medium. J. Tyndall demonstrated that such particles with incident white light, scatter blue light which is completely polarized at right angles to the incident beam. Lord Rayleigh proved that in the absence of all dust the light scattered by the molecules of air are sufficient to give a blue sky; and, added L. V. King, molecular scattering is sufficient to account completely for both the attenuation of solar radiation, and the intensity and quality of sky radiation. W. Spring considered the blueness of the sky to be due to the blue colour of the contained oxygen, ozone, and water vapour, since the rays which reach the eye, after reflection, and possibly after multiple reflections, will have traversed a longer path in the absorbing medium than the direct rays of the sun. It has just been shown, however, that the colour of the sky would be blue quite apart from selective absorption by oxygen or of its compounds. A bibliography on this subject has been compiled by N. E. Dorsey.

The **spark spectrum** of air is complex and is formed by the superposition of the spectra of its components. The relative intensities of some of the lines are altered by the partnership. A. J. Angström[18] found the spectrum showed mostly the lines of nitrogen, and it was quantitatively examined by D. Alter, A. Masson, and V. S. M. van der Willigen. The lines were measured by G. Kirchoff, W. A. Miller, W. Huggins, F. Exner and E. Haschek, P. W. Merrill and co-workers, A. Hagenbach and H. Konen, J. M. Eder and E. Valenta, F. Brasack, R. Thalén, L. de Boisbaudran, etc. J. Formanek gave for the more important lines in the spectrum of air 6563 in the red; 5943 and 5933 in the orange-yellow; 5711 and 5679 in the yellowish-green; 5535, 5496, 5454, 5177, 5046, 5006, 5003, and 4941 in the green; 4804, 4789, 4707, 4648, 4642, 4633, and 4606 in the blue; 4447, 4432, 4416, 4414, 4348, 4319, and 4241 in the indigo; and 4237, 4200, 4137, 4093, 4069, and 3995 in the violet. The effect of *pressure* was examined by L. Cailletet, A. Cazin, etc., who found the lines broadened with increasing press. A. Wüllner, and E. Goldstein examined the **band spectrum** of air. W. N. Hartley and W. E. Adeney, G. G. Stokes, J. Trowbridge and C. C. Hutchins, L. Ciechowsky, O. Neovius, J. J. Hopfield, and E. B. Frost and W. S. Adams examined the **ultra-violet spectrum** ; W. Schwetz, the **ultra-red spectrum** ; and J. Dufay, the spectrum of lightning.

The *aurora polaris*, or *aurora borealis*, or *aurora australis*, or *zodiacal light* is an imperfectly-understood luminous phenomenon of the upper atmosphere. It appears in various forms, being sometimes quiescent, and at others very changeable, showing arcs, bands, rays, curtains, patches, diffuse glows, and coronas. The colour is usually white, sometimes it is variegated red, yellow, or green. A great many observations have been made on the spectra of the different forms of the zodiacal light by J. R. Capron, H. Kayser, S. Arrhenius, etc. Much of the light is due to nitrogen bands, but the source of a green line $\lambda = 0.5577$ is not known. It has been attributed to krypton, but other krypton lines are absent, and it is considered very doubtful if sufficient krypton is present to produce so intense a line. The brilliant shifting auroral displays are usually accompanied by magnetic storms, and they are more numerous during years of sun-spot maxima than during years of sun-spot minima. It has been suggested that the aurora is produced by negative particles shot from the sun and entrapped by the magnetic field of the earth ; but L. Vegard and C. Störmer suggested that the phenomenon is produced by streams of positively charged α-particles in the upper atmosphere shot off by radioactive substances in the sun. They added that the green auroral line is due to the phosphorescence of solid nitrogen under the electronic bombardment, but J. C. McLennan could not verify this. The only line observed when solid nitrogen is bombarded by cathode rays is $\lambda = 5231$ A. J. C. McLennan, H. J. C. Ireton and K. Thompson, G. Caris, and D. A. Keys showed that the line is primarily due to oxygen, no oxygen, no 5577-line. Lord Rayleigh showed that the non-auroral light has its green line 5577 A., without the negative band spectrum of nitrogen, and it is suggested that it may be a phenomenon of phosphorescence excited by the sun in the day-time, and carried round by the earth's rotation.

G. D. Liveing and J. Dewar examined the **absorption spectrum** of liquid air. H. Buff reported that dry air absorbs 50 to 60 per cent. of the heat rays from a source at about 100°, and that the absorptive power of dry air exceeds that of moist air. J. Tyndall, on the contrary, found air to be quite diathermous. N. Egoroff examined the absorption of sunlight by the atm., and H. Wild showed that if dust be excluded, dry or moist air absorbs very little light.

C. G. Abbot and F. E. Fowle [19] estimate that of the total radiant energy delivered from the sun to the earth, about one-third—37 per cent.—is dissipated, for it is scattered into space by clouds, dust particles, or air molecules, and reflected from the surface of the earth. Of the remaining 63 per cent., about half is directly absorbed by the earth, and half by the atmosphere. In addition to the absorption or Fraunhofer lines inherent in the solar spectrum, there are many deficiencies resulting from the passage of solar energy through the earth's atm., and caused mainly by oxygen, ozone, carbon dioxide, and water vap. The three last named strongly absorb the long wave-length radiation from the earth. According to E. L. Nichols, the selective absorption of sunlight by the atm. is very marked. At 0.8μ, just beyond the visible red spectrum, about 8 per cent. of the sun's rays are cut off, while in the violet, at least half the light is absorbed ; it is for this reason too that the spectrum of solar light ends soon after the boundary of the visible spectrum is reached, and why many rays present in the spectra of artificial sources of light are absent from the solar spectrum. The eye is most sensitive to those rays which in the spectrum of sunlight are of maximum energy. Sunlight which has not been filtered through the atm. contains so much more ultra-violet radiation that it is necessary to protect the eyes by coloured glass at high altitudes. This is not only because of the excess glare above the snow line, but also because of the dangerous ultra-violet rays. Nitrogen and argon have no known absorption bands, and oxygen has only one band, and that is in the extreme ultra-violet or Schumann region. The absorption of light by air was examined by A. Kreusler, and E. Warburg. The reflecting power of the earth is small, and the atm. is nearly opaque to terrestrial radiations, and it is estimated that approximately 60 per cent. of the incident solar energy ultimately heats the earth's atm.

Bolometric observations show large water vapour absorption bands, and it is therefore inferred that most of the solar energy directly absorbed by the atm. is due to the water vap. All these absorption bands are of longer wave-length than the region of maximum intensity in the solar spectrum, so also are the absorption bands of carbon dioxide and ozone. The amount of solar energy absorbed by oxygen, nitrogen, and argon is negligibly small in comparison with the absorption due to water vap., ozone, and carbon dioxide. The absorption of terrestrial radiation by water vap., ozone, and carbon dioxide is indicated in Fig. 2, by C. G. Abbot and F. E. Fowle. The thick curve represents the energy distribution of radiation from a black body at 287·2° K. The area of this curve below the irregular full line near the top extending as far at least as 20μ shows the absorption of the earth's radiation by a column of 1·13 grms. of water vap. per sq. cm. cross-section as computed by H. Rubens and E. Aschkinass; this amount of water vap. was computed by C. G. Abbot and F. E. Fowle to be the average amount in the atm. as a whole above the 1780 metre level. The areas below the two broken curves show the absorption by carbon dioxide above the same level as computed by H. Rubens and E. Aschkinass, and C. Schäffer. The area below the dotted curve represents the absorption of the earth's radiation estimated from E. Ladenburg and E. Lehmann's observations. The absorption of the solar radiations by ozone plays an important part in the life of animals and plants. Thus, B. Moore said:

> As the light from the sun first strikes the earth's atm., perhaps one or two hundred miles above, it is full of ultra-violet light, and violet light. Such light rays as these, if they reached the earth at the present moment, would annihilate us; they would simply mean death to the world below. The first thing that happens to prevent this is that ozone is developed, and by absorption this ultra-violet light is shut out. The solar spectrum of sunlight is known to be marked out, to be limited, by the ozone developed in the upper atm., and it has been shown that if there were only a millimetre of ozone interposed between quartz plates nearly all this light, which is germicidal light, would be shut out. It is not completely shut out as the light passes through the air, and that is why there must be natural colour screens in plants and animals and man.

P. Lenard[20] showed that in addition to the **photoelectric effect** produced on a charged metallic surface struck by ultra-violet rays, there is a volume effect which takes place in the gas about the metal. The ionization is produced by the absorption of the ultra-violet rays by the gas itself. The effect with air was further studied by A. L. Hughes, T. Lyman, D. H. Loughridge, and F. Palmer. J. A. McClelland and J. J. M'Henry studied the nuclei produced in moist air by ultra-violet light; H. Kulenkampff, the ionization of air by X-rays and cathode rays. The **absorption of X-rays** from cathodes of different metals by air was studied by R. Whiddington, P. W. Burbidge, and G. Owen; the **scattering of X-rays** in air, by C. G. Barkla, C. G. Barkla and C. A. Sadler, and J. A. Crowther; the absorption of radiations emitted by a high resistance when traversed by an electric current, by G. Reboul; the mobilities of the ions in air, by M. Laporte; W. Kliefoth, the electrostriction effect; and A. H. Taylor and E. O. Hulburt, the absorption of radio-waves in the upper atmosphere.

The earth is not electrically neutral, for its surface is coated with a charge of negative electricity which gives rise to a positively charged electric field in the atm. Near the beginning of the eighteenth century, F. Hauksbee,[21] J. Wall, and S. Gray compared the discharge of electricity from a charged vessel across air to thunder and lightning; and in 1749, B. Franklin showed that "clouds that contain lightning are electrified." G. Beccaria made observations on atm. electricity extending over a number of years. L. G. le Monnier showed that tall insulated conductors become electrified when exposed to air with a clear sky; and C. A. Coulomb, and W. Linss found that the most perfectly insulated conductors lose their charges when exposed to air. These facts depend on the **electrical conductivity** of atm. air. The electrical state of the atm. produces the spectacular displays of lightning in thunderstorms, the aurora polaris, and St. Elmo's fire (*i.e.* a branch discharge from elevated objects).

According to L. A. Bauer and W. F. G. Swann, when the potential gradient at the surface of the earth is 100 volts per metre, the charge is 2·65 negative electrostatic units per sq. cm., or $4{\cdot}5\times10^5$ coulombs for the whole surface; and the net charge of the air is roughly 0·1 electrostatic unit of positive electricity per cubic metre. The **potential gradient** or the change of potential in rising one metre from the earth's surface is about 150 volts; it is rather less for the second metre, less again for the third, until about 10 kilometres high, it is practically zero. The potential gradient varies with location, being smaller in valleys than on the neighbouring ridges; it is generally smaller in tropical regions than in temperate climes; and it is larger in winter than in summer. The potential gradient is a minimum about 4 a.m., and may rise to a maximum about 9 a.m., and fall to a second minimum about 2 p.m., rising to a second maximum about 10 p.m., or there may be only one maximum at 2 to 4 p.m. Wind, smoke, dust, fog, rain, etc., modify and even reverse the normal potential gradient. C. Ramsauer also measured the decrease of potential vertically upwards from the earth.

L. A. Bauer and W. F. G. Swann gave $1{\cdot}44\times10^{-4}$ for the positive ion conductivity of air over land during clear weather, and for the negative ion conductivity, $1{\cdot}19\times10^{-4}$. The electrical conductivity of the atmosphere is thus extremely small if referred to that of copper as a standard. W. F. G. Swann estimated that a column of air one inch long offers as much resistance to the passage of the electric current as a copper cable 3×10^{16} miles long and of the same sectional area. Such a cable could be wrapped round the earth 8×10^{11} times, and would stretch from here to Arcturus and back about 20 times. The conductivity is generally greater during summer than during winter; and usually high in the morning and low in the evening; it is small when the air is dusty or foggy, and relatively high when the air is clear and dry. The conductivity varies irregularly during the first kilometre elevation, but above that level it increases rapidly, and at 6 kilometres elevation it has 20 times its surface value. According to W. J. Humphreys, the sporadic electric currents, produced in the atm. by lightning discharges, may amount to many thousand ampères; and those due to falling rain, snow, hail, etc. average 10^{-16} amp. per sq. cm. in ordinary rain, but with rain accompanied by thunderstorms, as much as 10^{-2} amp. per sq. cm. has been reported. There are also two forms of electric currents which are always flowing. One is produced by the mechanical or convective transfer of ions from one place to another by winds, etc. The average amounts to 10^{-16} amp. per sq. cm. with the wind passing at a metre per second. The other is due to the downward flow of one kind of ions—generally positive—and the upward flow of ions of the opposite kinds. The average conductive current produced in this way amounts to 3×10^{-16} amp. per sq. cm. R. A. Millikan and I. S. Bowen investigated the conductivity of air at altitudes from 5 to 15·5 kms. The subject was discussed by V. F. Hess, *Die elektrische Leitfähigkeit der Atmosphäre und ihre Ursachen* (Braunschweig, 1926); E. Mathias, *Traité d'électricité atmosphérique et tellurique* (Paris, 1924); and by B. Chauveau, *Électricité atmosphérique* (Paris, 1922). T. A. McLaughlin studied the **cataphoresis** of air-bubbles in various liquids.

According to modern theories, the conductivity of atm. air is produced by ions. C. T. R. Wilson, and H. Geitel discovered that spontaneous **ionization** occurs in the atm.; and E. Rutherford and H. L. Cooke, and J. C. McLennan and E. F. Burton showed that the lower atm. has penetrating rays presumably derived from radioactive substances near the surface of the earth. A. Gockel attributed the ionization of the atmosphere to the influence of the sun as shown by the diurnal and annual variations in the conductivity. P. Langevin also found the existence of large ions of molecular size moving with a comparatively small velocity. These ions are probably the charged nuclei of cloudy condensation discussed by J. Aitken, J. W. Broxon, H. Kulenkampff, G. A. Anslow, W. W. Merrymon, V. I. Baranoff,

J. J. Nolan, J. J. Nolan and J. Enwright, E. Marsden, W. Kohlörster, A. D. Power, J. F. Lehmann and T. H. Osgood, J. Clay, H. A. Erickson, F. Behounek, M. Akiyama, R. A. Millikan and R. M. Otis, F. Ramon y Ferrando, A. Wigand, L. B. Loeb, A. Stäger, A. L. McAulay and N. L. Hutchinson, K. M. Downey, A. Steichen, W. F. G. Swann, A. Pannekoek, R. Glocker and L. M. Valasek. R. A. Millikan and G. H. Cameron, and G. M. B. Dobson studied the ionization of air.

J. Elster and H. Geitel found that a bare wire exposed to air and negatively charged gradually acquires a coating of radioactive material, and H. A. Bumstead found that the radioactive material of the atm. consists essentially of radium and thorium emanations. L. A. Bauer and W. F. G. Swann estimate that the **radioactivity** of air over the Pacific Ocean is eq. to $3{\cdot}3\times10^{-12}$ curie of radioactive emanation per cubic metre; over the Subantarctic Ocean, $0{\cdot}4\times10^{-12}$ curie; and over the land, an average of 88×10^{-12} curie. From E. Rutherford's estimate of the vol. of curie of emanation, the respective vols. of emanation are $1{\cdot}95\times10^{-19}$, $0{\cdot}24\times10^{-19}$ and $51{\cdot}9\times10^{-19}$ part of the atmosphere. These amounts do not suffice to maintain the ionization of atm. air over the oceans, and probably only a part of that over the land—*vide* **4.** 26, 3. It has been estimated that 2 to 6 pairs of positive and negative ions are produced in each c.c. of atm. air per sec. The conc. of the ions does not increase indefinitely because when the conc. reaches 2400 of each kind per c.c. the rate of combination of the ions to form neutral molecules is equal to the rate at which the ions are formed. According to A. S. Eve's estimate, the radioactive material in the earth can account for the production of 4·35 ions per c.c.

	+ ions per c.c.	− ions per c.c.
Mean of land observations	737	668
Mean of sea observations	770	632

E. Rutherford and H. L. Cooke, and J. C. McLennan and E. F. Burton found that air freed from radioactive air and confined in a hermetically sealed vessel, over land, spontaneously forms about 10 ions per c.c. per sec. This is due to the penetrative γ-radiations derived from the radium and thorium, and their disintegration products in the soil. Over the sea, where there is practically no radioactive material, the ions are formed at the rate of 4 ions per c.c. per sec. in a copper or zinc vessel. W. Kolhörster found that with increase of altitude, the ionization within the closed vessel decreases up to an altitude of about 700 metres, showing that the conductivity of the air is produced by the γ-radiations from the radioactive matters in the earth. Above 700 metres, however, the speed of ionization increases rapidly with increasing altitude, until, at 9000 metres, the ions are produced at the rate of 80 per c.c. per sec., and probably higher values at higher altitudes. This suggests a radiation from a source external to the globe or from some agency in the upper regions of the atm. F. Linke says that a layer of strongly radioactive cosmical dust is present in the atm. at an altitude of 20 kms. The ionization of air over the ocean and land is probably due to this cause; while the additional ionization over the land is derived from the radioactivity of the soil—*vide* **4.** 26, 3. S. Chapman and E. A. Milne showed that if the α-particles, at the outer fringes of the atmosphere, possess velocities of the same order as those observed with radioactive substances, if directly incident from outside, the fastest could penetrate to a height of 80 kms. and the slowest 85 kms., and this is independent of the level at which diffusive separation is supposed to commence, and of the presence or absence of hydrogen. This result is to be contrasted with that of L. Vegard, who found that the height reached would be 200 kms. for α-particles with the initial velocity of those from radium-C. The importance of these results is in their bearing on the theory of auroras (which are confined to the 100 kms. to 130 kms. layer); it assumes that they are the manifestation of the absorption by the atm. of α-particles emitted by the sun. The penetration of the atmosphere by β-rays and γ-rays would give rise to well-marked layers of maximum ionization at about 54 kms. and 26 kms. respectively. G. Hoffmann said that there is nothing mysterious about the penetrating radiations at sea-level, for they are derived from known radioactive elements. The origin of the high frequency radiation was discussed by V. F. Hess, R. A. Millikan, F. Behounek, W. Kolhörster, E. Rutherford, W. F. G. Swann, etc. A. Wigand believed that the penetrating radiation of the higher atmosphere has a wave-length shorter than the γ-rays. The radioactivity of air was also studied by W. Schmidt, R. A. Millikan and G. H. Cameron, and L. N. Bogoiavlensky and A. A. Lomakin.

The earth is continually losing negative electricity owing to its potential gradient in a conducting atmosphere. The current from a sq. cm. of the earth's surface is about 2×10^{-16} amp., and from the whole earth, about 1000 amps., and this supply maintains 90 per cent. of the earth's charge which would disappear in 10 minutes if not replenished. If the negative charge of the earth's surface can be explained, there is no need to account for the positive charge of the atmosphere. The conductivity of the atm. increases with altitude, and at 9 kms. its atm. has thirty times the conductivity it possesses at the earth's surface. Hence, with a constant potential gradient, more negative electricity would be driven onward than would be driven from the earth into the atmosphere. Hence, the shell of air below 9 kms. would become positively charged, and the potential gradient would be accordingly reduced. This process would continue until the decrease of the potential gradient with altitude just compensated for the increased conductivity. G. C. Simpson suggested the earth's charge is maintained by the emission of positive and negative corpuscles of a high penetrative power of the sun; the penetration power of the negative corpuscles is greater than that of the positive ones, and sufficient to enable them to reach the earth's surface charging it negatively; while the positive corpuscles are caught by the atmosphere charging it positively. C. T. R. Wilson suggested the ions in the atm. act as nuclei for the condensation of water; and since water condenses more readily on negative than on positive ions, the rain should be charged negatively, the atmosphere positively. As a matter of fact, rain is sometimes charged positively and sometimes negatively—but 75 per cent. of the charge is positive, *i.e.*, of a sign opposite to that required by theory. H. Ebert, and J. Elster and H. Geitel noted that the negative ions of the atm. diffuse more rapidly than the positive ions, so that, with the barometer falling, the highly ionized air in the ground, by a kind of atmolysis, emerges with a positive charge. G. C. Simpson, W. F. G. Swann, and H. Gerdein have shown that this hypothesis is quite inadequate. W. H. Bragg observed that when the γ-rays ionize a gas, the electrons emitted are shot off in the direction of the incident γ-ray. The more penetrating the radiation the greater the effect. Hence, argued W. F. G. Swann, when the penetrating γ-radiations ionize air from above downwards, most of the negative electrons which are emitted will be travelling downwards before they come to rest. Hence, the earth's surface, receiving the negative electrons, will acquire a negative charge, and the atmosphere a positive charge.

H. Ebert, and G. Hoffmann found that liquid air is a non-conductor of electricity, but if pieces of metal be placed therein, an electric charge is acquired. The liquid loses this property if filtered, but acquires it again when exposed to the atm. Water is absorbed, and the friction of the contained ice gives the metal a negative charge while the ice requires a positive charge. The residual ionization of air was measured by W. W. Merrymon. The nature of the ions in air was discussed by H. A. Erikson; and the mobilities of ions in mixtures of air and ammonia, by L. B. Loeb and M. F. Ashley.[22] J. Chadwick and K. G. Emeléus, I. Curie, and L. Meitner and K. Freitag studied the tracks of the α-particles in air. The ionization of air by oxidation processes has been discussed by W. P. Jorissen and W. E. Ringer, and by R. Schenck and co-workers—*vide* **4.** 26, 1. The mobilities of ions in air was discussed by J. J. Nolan, H. A. Erikson, and W. B. Haines; the consumption of energy in the ionization of air, by L. Grebe, and L. Frebe and L. Kriegesmann; the attachment of electrons to the molecules of air, by V. A. Bailey; the transformation period of the positive ions, by L. M. Valasek; the loss of energy of the α-particles in air, by P. L. Kapitza; the ionization of air by electrons, and α-rays, by L. Grebe, T. R. Wilkins, J. F. Lehmann and T. H. Osgood, and G. A. Anslow; the production of β-rays in air by X-rays of short wave-length, by H. Ikeuti. For the **velocity of the ions** in an electric field with a potential difference of one volt per cm., J. Franck gave, for positive ions in dry air at about 15°, and 760 mm. press., 1·35 cms. per second, G. Rothgiesser, 1·331 cms. per second. For negative ions, J. Franck gave 1·82, and G. Rothgiesser, 1·927 cms. per second. With moist air, at 15°, the latter gave 1·325 cms. per second for positive ions and 1·610 cms. per second for negative ions. The **speed of electrons** in air was measured by A. Becker, P. Lenard, A. M. Tyndall and G. C. Grindley, L. B. Loeb, W. Busse, H. B. Wahlin, H. R. Hasse, and J. Robinson. For the **diffusion coefficient of ions** in moist air, J. Townsend gave 0·032 sq. cm. per second for positive ions and 0·035 sq. cm. per second for negative ions; and in dry air, he obtained 0·028 sq. cm. per second with positive ions and 0·043 sq. cm. per second for negative ions. E. Rutherford, J. Franck and W. Westphal, and E. Salles obtained similar data. The **rate of recombination of ions**, $dn/dt = an^2$, where n denotes the conc. of the ions, represented by the ratio a/e, when e denotes the elementary charge in electrostatic units, values ranging from 3200 to 3500—mean, 3368—have been obtained by J. Townsend, R. K. McClung, P. Langevin, L. Hendren, H. A. Erikson, H. Thirkill, H. Ogden, and H. Seeman. W. Busse discussed the monomolecular ions in air; and L. M. Valasek found the rate of change from that of newly formed positive ions with a velocity of 1·87 cm. per sec. to ions with a velocity of 1·37 cm. per sec.

The resistance of the air to the passage of a spark was examined by A. Overbeck,[23] T. Holmen, Lord Kelvin, A. Heydweiller, E. Hospitalier, C. P. Steinmetz, E. Jona, etc. The **discharge tension** of the current required for spherical electrodes at different distances apart in air at different press. has been the subject of many investigations. A. Orgler found with air at different press., p, and with 0·1 and 0·5 cm. spark gaps, the tension required for the discharge was:

p . . .	750	650	450	250	100	60	20 mm.
Kilovolts (0·5) .	17·450	15·470	11·420	7·116	3·579	2·505	1·266
Kilovolts (0·1) .	4·566	4·062	3·120	2·040	1·092	0·795	—

The structure and form of the sparks were studied by T. Terada and U. Nakaya; the point discharge, by J. Zeleny, and W. C. Röntgen; the discharge with cylindrical electrodes, by J. B. Whitehead and co-workers, S. P. Farwell, E. A. Watson, J. W. Broxon, and F. Schaffers; the corona discharge in air, by C. H. Wills; the glow discharge, by W. Stephenson; and the electrodeless discharge, by E. Bouty, and H. Wagner. The potential difference of the cathode for the glow discharge with electrodes of different metals in air was measured by K. Rottgardt,[24] A. Schaufelberger, E. Warburg, and C. A. Skinner. E. Meyer studied the effect of traces of impurities; H. Stücklen, the effect of moisture on the sparking potential of air; and F. Gross, the cathodic spluttering. F. Fernie studied the electrical break-down of air; A. Günther-Schulze, and K. G. Emeléus, the distribution of potential in the glow discharge in air; E. F. Burton, the spark potential; and H. Fischer, the discharge with Tesla currents. J. Estalelle, A. Plante, L. Schopenhauer, and E. Mathias discussed the effect of lightning on atm. air.

The **dielectric constant** of atm. air was found by L. Boltzmann[25] to be 1·000590 at 1 atm. press. and 0°; K. Tangl gave 1·01080 at 19° and 20 atm.; 1·03281 at 60 atm.; and 1·05494 at 100 atm. press.; H. Riegger, 0·001902 at −185·5°; A. P. Carman and K. H. Hubbard, 1·000594 at 0° and 760 mm.; and E. C. Fritts, 1·000540. For liquid air at the b.p. and atm. press., M. von Pirani gave 1·432 for $\lambda = \infty$; and U. Behn and F. Kiebitz gave 1·47–1·50 for $\lambda = 75$. A. Russell expressed the dielectric properties of air as 38–39 kilovolts per cm.; J. J. Thomson, 30; M. O'Gorman, 27; and C. P. Steinmetz, 38·2. W. Kliefoth observed the **electrostriction**, or contraction in vol., which occurs on applying a powerful electrical field, showing that the attraction between the molecules of air has an electrical origin. Values for the **magnetic susceptibility** of air ranging from $+0{\cdot}024 \times 10^{-6}$ to $+0{\cdot}03085 \times 10^{-6}$ have been reported by G. Quincke,[26] H. du Bois, J. A. Fleming and J. Dewar, P. Curie, R. Hennig, T. Soné, and

W. P. Roop—for air at atm. press. and 16° to 22°; for air at 40 atm. press., G. Quincke gave $1{\cdot}3\times10^{-6}$ mass units; V. I. Vaidyanathan gave $0{\cdot}029\times10^{-9}$ vol. units at ordinary temp. and at a low press.; and for air at 182°, J. A. Fleming and J. Dewar gave $0{\cdot}28\times10^{-6}$ mass units; E. Lehrer, $24{\cdot}16\times10^{-6}$ absolute values; and G. W. Hammar made observations on this subject. W. Schütz, and K. S. Krishnan observed no orientation of the atoms in a magnetic field.

N. T. de Saussure[27] said that 100 vols. of water at 15° absorb about 5 vols. of atm. air at 760 mm. press. The **solubility** of air in *water* has been studied by O. F. Tower, W. Dittmar, E. Wiedemann, W. French and F. Ashworth, K. Angström, W. E. Adeney and H. G. Becker, J. H. Coste, R. Bunsen, H. E. Roscoe and J. Lunt, H. E. Hamberg, H. Tornöe, B. Schulz, and O. Petterson and K. Sondén. J. Metschl discussed supersaturated soln. of air in water. According to L. W. Winkler, 1000 c.c. of water dissolve the proportions of oxygen and nitrogen indicated in Table IX; the air was freed from carbon dioxide and ammonia. The barometer was normal. Nitrogen includes argon and other inert gases. The results of A. Mallet were discussed in **1.** 10, 5. J. Porter measured the solubility of air at normal press. in purified and in alkaline water at various temp. He found that more air remains in the water than corresponds with its solubility, and this air is evolved only when the temp. is raised above 80°. It is suggested that this air is not in an unstable supersaturated condition, but it forms a layer firmly bound to the surface of the vessel so that it has no appreciable vol. This air can be liberated provided the temp. be kept at 60° for 2 or 3 hrs. J. Porter also measured the rate at which air is absorbed from the atm. by de-aerated water. W. Dittmar, H. Tornöe, and H. E. Hamberg examined the solubility of air in sea-water; O. F. Tower, in dil. and conc. *sulphuric acid.*

TABLE IX.—THE SOLUBILITY OF AIR IN WATER.

Temp.	O_2 c.c.	N_2 c.c.	Total c.c.	Per cent. O_2 in dissolved air.	Temp.	O_2 c.c.	N_2 c.c.	Total c.c.	Per cent. O_2 in dissolved air.
0°	10·19	18·99	29·18	34·91	16°	6·99	13·35	20·14	34·31
2°	9·64	18·05	27·69	34·82	18°	6·61	12·77	19·38	34·12
4°	9·14	17·18	26·32	34·74	20°	6·36	12·32	18·63	34·03
6°	8·68	16·38	25·06	34·65	22°	6·11	11·90	18·01	33·95
8°	8·26	15·64	23·90	34·56	24°	5·89	11·49	17·38	33·86
10°	7·87	14·97	22·84	34·47	26°	5·67	11·12	16·79	33·77
12°	7·52	14·35	21·87	34·38	28°	5·46	10·75	16·21	33·68

Conc. of H_2SO_4	98	90	80	70	60	50
Solubility	0·0173	0·0069	0·0069	0·0055	0·0059	0·0076

A. von Antropoff found air to be soluble in *aniline* and in *acetic acid;* F. Dolezalek, in *benzene;* and A. Christoff, in *ethyl ether*—such that one vol. of ether absorbs 0·290 vol. of air at 0° and 760 mm.; 0·287 vol. at 10°; and 0·286 vol. at 15°. According to S. Robinet, 100 vols. of 95 per cent. *alcohol* dissolve 14·1 vols. of air; *petroleum,* 6·8 vols.; *benzene,* 14·0 vols.; *oil of lavender,* 6·9 vols.; *oil of turpentine,* 24·2 vols. The **adsorption** of air by *charcoal* has been studied by K. Siebel.[28] F. Bergter, E. Berl and K. Andress, J. Chappius, A. B. Lamb and co-workers, V. Lefebure, S. McLean, H. B. Lemon and K. Blodgett, and A. Piutti; *indiarubber,* by H. A. Daynes, T. Graham, C. G. Hüfner, and V. Lefebure; J. D. Edwards and S. F. Pickering found that if the permeability of rubber for hydrogen is unity, the value for air is 0·22. The adsorption of air by *zeolites* was studied by C. Friedel; *chabasite,* by R. Nacken and L. Wolff, and R. Seeliger; *soils,* by E. Reichardt, and H. E. Patten and F. E. Gallagher; *salts,* by P. A. Guye and N. Zachariades; *silver bromate,* by J. H. Reedy; *silver halides, silver phosphate* and *iodine pentoxide,* by T. W. Richards and G. P. Baxter; *benzoic acid,* and *potassium chloride*, by A. Scott; *copper oxide*, by P. A. Guye and N. Zachariades; and *celluloid, viscose*, or *artificial silk*, and *gelatin*, by V. Lefebure.

§ 3. The Discovery of Nitrogen

> Le mérite de la découverte d'une vérité appartient tout entier à celui qui la démontre. —P. S. de Laplace.

It is difficult to state precisely who first isolated nitrogen and clearly recognized it as a definite substance. In his experiments on combustion or burning (**1**. 1, 13–16), John Mayow, during his investigation on nitre, got very near, if he did not get actually there. Several others also were not far away from the discovery. As G. F. Rodwell[1] pointed out, the man who deduces on good mental evidence, or even proves by actual experiment, the existence of something not known before is not always recognized as the discoverer ; but rather is hailed discoverer he who proves by a conclusive series of experiments that the substance in question has properties, *sui generis*, distinct from all other substances. *He alone discovers who proves.* Otherwise, Boyle or Paracelsus would be called the discoverer of hydrogen ; Lucretius, of carbon dioxide ; J. Kunckel, of ammonia ; Eck de Sultzbach, of oxygen ; Hooke or Cassini, of the law of gravitation ; etc. D. Rutherford is generally credited with the discovery of nitrogen. It appears that Joseph Black, having noticed that a residue was left after the combustion of carbonaceous bodies in air, and the absorption of fixed air produced by the combustion, suggested to one of his pupils, Daniell Rutherford, the desirability of an investigation on this subject. In 1772, D. Rutherford published a thesis entitled: *Dissertatio inaugauralis de aere fixo dicto aut mephitico* (Edinburgh, 1772), in which he said :

> By the respiration of animals, healthy air is not merely rendered mephitic but it also suffers another change, for after the mephitic portion is absorbed by solution of caustic alkali, the remaining portion is rendered salubrious ; and although it occasions no precipitate in lime water, it nevertheless extinguishes flames, and destroys life.

D. Rutherford thus removed oxygen from the air by such combustibles as phosphorus, charcoal, etc., and washed out the products of combustion by alkali-lye or lime-water. The residue was called by him *phlogisticated air ;* hydrogen was also called phlogisticated air. D. Rutherford believed that nitrogen was produced when the burning body gave up some of its phlogiston to the air ; while hydrogen was produced by the union of phlogiston with atm. air.

In the manuscript papers of H. Cavendish, there is one which he marked " communicated to Dr. Priestley," and which is acknowledged by J. Priestley in his paper on *Airs*. Here, H. Cavendish clearly distinguished nitrogen from other kinds of unrespirable and incombustible gases, and proved by experiment that atm. air consists of two parts, one of which in the combustion of charcoal is converted into fixed air, and the other is a mephitic air *sui generis*. He said :

> The natural meaning of *mephitic air* is any which suffocates animals . . . but in all probability there are many kinds of air which possess this property. . . . I transferred some common air out of one receiver through burning charcoal into a second receiver . . .

the air in the second receiver was passed back again through fresh burning charcoal into another receiver . . . the fixed air formed in each case was absorbed by sope leys. The 180 oz. measures of air in the first receiver was reduced to 162 oz. measures of this mephitic air. The sp. gr. of this air was found to differ very little from that of common air ; of the two it seemed rather lighter. It extinguished flame, and rendered common air unfit for making bodies burn, in the same manner as fixed air, but in a less degree, as a candle which burnt about 80 sec. in pure common air, and which went out immediately in common air mixed with $\frac{6}{55}$th of fixed air, burnt about 26 sec. in common air mixed with the same portion of this burnt air.

H. Cavendish called this residual air *mephitic air*, and added :

In all probability there are many kinds of mephitic air. I am sure there are two—namely fixed air, and common air in which candles have burned, or which has passed through the fire. Air which has passed through a charcoal fire contains a great deal of fixed air which is generated from the charcoal, but it consists principally of common air which has suffered in its nature from the fire.

It is estimated that the nitrogen thus prepared by H. Cavendish contained about one-tenth of carbon monoxide. The portion of the air—oxygen—which has disappeared in this experiment was supposed to have been absorbed by the fumes of the burning charcoal. The recognition of the inert gases in atm. air was discussed in the chapter on the inert gases.

A. L. Lavoisier first called the residual gas *la moufette atmosphérique*, and afterwards *azote;* C. W. Scheele, *verdorbene Luft ;* and J. A. C. Chaptal de Chanteloup suggested the name *nitrogène*—from *νίτρον*, saltpetre ; and *γεννάω*, I produce—because the gas is a constituent of nitre. The Germans call it *Stickstoff*. The term *azote* may be derived from the alchemical term *azoth*—possibly made up from the initial letter *a* of the Latin, Grecian, and Hebraic alphabets, and the last letters of these alphabets—referring to a hypothetical *mercury of wisdom*—whatever that may mean. A. Libavius said that *azoth* may be derived from an old Spanish-Arabian term *azoque* or *azoc* for mercury ; and that the term may even be an abbreviation of *μυστήριον ἄζωτον*, the revealed secret.

§ 4. The Occurrence of Nitrogen

Nitrogen is the dominant element in air. The gas being a little soluble in water, it is also found dissolved in sea-waters, rivers, and rain-water. Nitrogen also occurs in mineral waters, and in the gases derived from these springs. Thus, R. Bunsen[1] reported 99·5 per cent. nitrogen in the gases from the geysers in North Iceland ; J. L. Smith, 97 per cent. in the gas from the Yalova springs, Asia Minor ; M. Bamberger and A. Landsiedl, 94·83 per cent. in the gases from the Vöslau springs near Vienna ; E. Ludwig, 84·83 per cent. in the gas from Olovo ; P. Bourcet, 61·16 per cent. in the gas from Joule, Jura ; E. Ludwig, 5·44 per cent. in the gas from the springs in the vicinity of Banjaluka ; and F. Ragsby, 0·45 per cent. in the gas from the springs at Mont Dore. Other observations have been made by C. Moureu, A. Purgotti and G. Anelli, C. Bouchard and A. Desgrez, R. Nasini and F. Anderlini, H. Siegmund and P. Juhasz, G. Carrara, E. Ludwig and R. von Zeynek, H. Wurtz, M van Breukcleven, F. Parmentier and A. Hurion.

Variable quantities of nitrogen have been reported in the gases of volcanic origin by T. Schlösing.[2] H. Davy reported nitrogen in the gas from inclusions in rocks. W. F. Hillebrand found the gas occluded in uranite, etc.—*vide* helium. W. N. Hartley, W. A. Tilden, and G. Tschernik found the gas in a number of rocks and minerals—*e.g.* sapphire, topaz, coal, lignite, etc.; A. Gautier, in granite, porphyry, etc.; and C. Erkin, in sandstone, oolites, marls, fuller's earth, etc. A. Delesse reported 0·008 per cent. in green fluorspar; 0·002, in smoky quartz; 0·03, in opal; 0·012, in Iceland opal; 0·007, in chalcedony; 0·004, in emerald; 0·022, in topaz; 0·01, in barytes; 0·026, in gypsum; 0·015, in Iceland spar, and in stalactites; 0·019, in iron spar; and 0·017, in smithsonite. The nitrogen was not an accidental infiltration from the surface. Very little was found in pyroxene, garnet, mica, talc, steelite, and zeolites. J. Parry, and A. H. Allen, etc., showed that iron and steel contain some occluded nitrogen. O. Silvestri reported it occurring as iron nitride in some fresh lava from Etna; and J. B. J. D. Boussingault found it to the extent of 0·011 per cent. in the occluded gas of the meteoric iron from Lenarto.

T. W. Richards found that nitrogen occurs in traces in many oxides prepared by the calcination of nitrates. Nitrogen occurs in numerous chemical compounds —*e.g.* nitrates, ammonium salts, alkaloids, etc. A. F. de Fourcroy[3] found nitrogen in the swimming bladder of the carp. Nitrogen occurs combined in ammonia, nitre, and a great many animal and vegetable products—*e.g.* white of egg, proteids, etc. It is a constant and essential constituent of all living organisms; all life seems to depend upon the transformation of proteid compounds. J. Davidson studied the change in the nitrogen content of wheat seedlings during germination and growth; and R. Combes, the accumulation of nitrogen by the foliage, stem, and roots of a two-year-old beech during 16 months' growth.

C. A. Young, H. Draper, C. Fievez, A. Fowler and C. C. L. Gregory, etc., observed that nitrogen lines occur in the spectrum of the sun; but, as shown by M. N. Saha, the evidence is not conclusive, and he added that although no lines of nitrogen occur in the solar spectrum, the presence of nitrogen is revealed by the existence of cyanogen bands. This question was also discussed by F. E. Baxandall, and W. H. Wright.

§ 5. The Preparation of Nitrogen

Nitrogen is easily obtained from air by removing the admixed carbon dioxide and oxygen. This is conveniently done by burning a piece of phosphorus in a dry crucible floating on the surface of water under a small bell-jar. The phosphorus combines with most of the oxygen, forming phosphorus pentoxide, and this quickly dissolves in water, leaving behind the nitrogen. If the water be alkaline with sodium hydroxide, the carbon dioxide, normally present in air, will also be removed. The nitrogen so prepared is not pure because the phosphorus ceases to burn before all the oxygen has been removed. A soln. of cuprous chloride in hydrochloric acid rapidly absorbs oxygen from air, and leaves behind the nitrogen—*vide supra*, the analysis of atm. air. It is best to remove the carbon dioxide by first passing the air through a soln. of sodium hydroxide; and to absorb the oxygen by means of an element which will form a non-volatile oxide. C. Brunner,[1] and G. Spencer used red-hot reduced iron. Copper is generally considered best for the purpose; the " turnings " offer a large surface of oxidizable metal to the air. This agent was employed by J. B. A. Dumas and J. B. J. D. Boussingault, R. Bunsen, P. von Jolly, A. Leduc, T. Welton, O. Franke and O. Finke, Cyanid-Gesellschaft, L. Carius, and R. Threlfall. M. Berthelot removed the last traces of oxygen by chromous chloride—*vide supra*—and H. Deslandres by molten sodium. The general process is as follows:

Air freed from carbon dioxide in a wash bottle of sodium hydroxide, *A*, Fig. 3, and from moisture by passage through sulphuric acid, *B*, is then passed through a red-hot tube containing copper turnings. The copper removes the oxygen and forms cupric oxide: $2Cu+O_2=2CuO$. The nitrogen passes on to be collected in a gas jar, or gasholder, etc. In the diagram, the air is supposed to be drawn over the copper, the gasholder being filled with nitrogen. If the gasholder were placed at the end A, and air forced along the tubes, the nitrogen gas could be collected in gas jars, Fig. 3. Cold boiled water should be used in the gasholder so as to lessen the risk of contamination owing to the presence of oxygen dissolved in ordinary water.

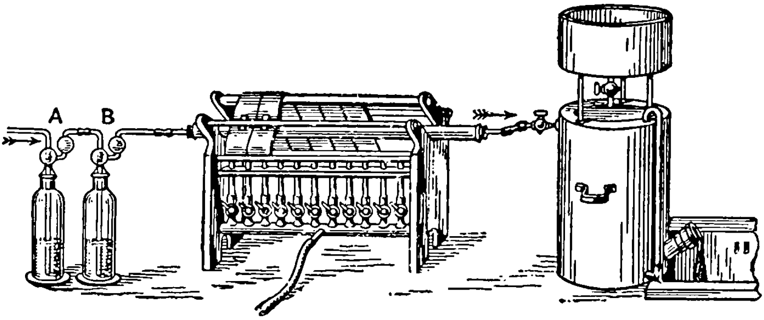

FIG. 3.—Preparation of Nitrogen.

The process of oxidation of course ceases when all the copper is oxidized. If the air, before passing over the red-hot copper, be led through an aq. soln. of ammonia, as recommended by S. Lupton, the ammonia reduces the copper oxide as fast as it is formed: $2Cu+O_2+nN_2=2CuO+nN_2$; and $3CuO+2NH_3=3Cu+3H_2O+N_2$. Any excess of ammonia can be removed by passing the gas from the copper tube through a soln. of sulphuric acid before it is collected in the gasholder. This process was suggested by A. G. V. Harcourt, and used by S. Lupton, H. Biltz, M. Berthelot, R. Threlfall, W. L. Badger, etc. C. van Brunt devised the apparatus illustrated, Fig. 4, for obtaining nitrogen from the air by the copper-ammonia process. A mixture of equal vols. of a sat. soln. of commercial ammonium carbonate and ammonia of sp. gr. 0·93 is introduced into the vessel *A*, and copper turnings in the cylinder *B*. A current of air is directed into the inlet tube, and this ensures the circulation of the liquid in the apparatus *viâ C*, the speed of flow of the liquid being regulated by the clamp *D*. The air discharged in the cylinder *B* is freed from oxygen by the copper and ammonia. The ammonia is removed from the nitrogen by scrubbing the gas from the exit tube with dil. sulphuric acid. W. L. Badger modified the apparatus using also a soln. of ammonia sat. with ammonium chloride.

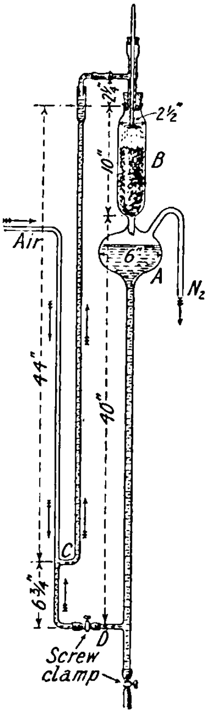

FIG. 4.—Nitrogen by the Ammonia-Copper Process.

G. A. Hulett passed a mixture of hydrogen and air over heated copper; and observed that the hydrogen reduced the copper oxide as fast as it was formed: $2Cu+2H_2+O_2+nN_2=2Cu+2H_2O+nN_2$. A number of processes have been devised—by A. Frank and N. Caro,[2] D. Lance and E. G. Elworthy, J. D. Riedel, H. Braun, J. Harger, the Société l'Oxyhydrique Française, F. A. Rudolf, the Cyanid-Gesellschaft, C. E. Acker, etc.—for removing the carbon dioxide and water from flue gases, etc., so as to leave the nitrogen as a residue. E. Romanelli burnt hydrogen in air to remove the oxygen; the Elektrizitätswerk Lonza used ammonium hydrosulphite as absorbent, followed by combustion with hydrogen. F. J. Metzger obtained nitrogen—free from oxygen—for annealing metals, etc., by adding a combustible gas—*e.g.* hydrogen—and bringing the mixture under high press. in contact with carborundum at about 400° so as to maintain the combustion of the combustible gas with oxygen. The combustion products are then separated by condensation. J. E. Bucher described a process in which coke-oven gas is passed over copper at 450°. The oxygen forms copper oxide which is subsequently reduced by the coke-oven gas. G. Kassner removed the oxygen from air by absorption with calcium plumbite, alkali manganite, etc. H. Kautsky and H. Thiele forced air through a porous membrane in a soln. of sodium hyposulphite when all but 0·0007 per cent. of oxygen was removed from the nitrogen. V. Oehlmann removed the oxygen by passing air over pieces of calcium sulphide moistened with a soln. of an iron salt.

The preparation of nitrogen by the fractional distillation of liquid air was discussed in the first volume (**1**. 13, 25). Several processes for conducting this operation have been patented.[3] G. J. Merturi separated the components of air by diffusion through rubber, etc.—*vide* atmolysis. Nitrogen obtained from the atmosphere is, of course, contaminated with argon and the inert gases. This is not the case with nitrogen from compounds containing the gas in combination with other elements. In 1789, A. F. de Fourcroy [4] noted that when chlorine gas is passed into an excess of aq. ammonia, nitrogen is evolved; if the ammonia be not in excess, the violent explosive nitrogen chloride (*q.v.*) is formed. A. Anderson said that the product is always contaminated with oxygen. If a soln. of aq. ammonia or ammonium salt be treated with a hypochlorite or hypobromite, nitrogen is again produced. A. Fauconnier said that in this reaction a part of the ammonia is converted into nitrous acid. In conducting the process, a soln. of ammonia is treated with bleaching powder in soln. or, as recommended by G. Neumann, compressed into cubes. F. C. Calvert used 200 c.c. of a soln. of bleaching powder containing 5 per cent. of hypochlorite, and mixed with 1·146 grms. of ammonium sulphate. E. Marchand employed ammonium chloride in place of the sulphate. H. P. Waran made nitrogen by dropping bromine into aq. ammonia. Lord Rayleigh found that a trace of nitrous oxide is always formed when nitrogen is prepared by the action of hypobromites or hypochlorites on urea, or other acid amides. F. C. Calvert noted the formation of nitrogen when organic substances, like gelatine, albumin, glue, soap, etc., are treated with hypochlorites. G. J. Fowler observed that nitrogen is formed when iron nitride is treated with chlorine. D. Chattaway and K. J. P. Orton found that a soln. of nitrogen iodide in an organic solvent decomposes with the evolution of nitrogen; and that the nitrogen hydroiodides furnish the same gas when exposed to light, or treated with water or alkali-lye.

B. Corenwinder[5] showed that when an aq. soln. of ammonium nitrite is heated, nitrogen gas is evolved: $NH_4NO_2=2H_2O+N_2$; better results are obtained with a mixture of ammonium chloride and a conc. soln. of alkali nitrite. The product always contains a trace of nitric oxide, and O. W. Gibbs stated that this contamination can be avoided by washing the gas with an excess of a conc. soln. of potassium dichromate and acetic acid which converts the impurity into nitric acid. J. P. Emmet added a piece of zinc to molten ammonium nitrate and obtained a brisk evolution of nitrogen. C. Winkler found that when a mixture of ammonium nitrate and phosphorus is heated, nitrogen is evolved: $2P+5NH_4NO_3=2H_3PO_4+5N_2+7H_2O$. E. J. Maumené warmed a mixture of ammonium nitrate and chloride and washed out the chlorine from the mixture of gases which was evolved; E. Soubeiran employed a mixture of potassium nitrate and ammonium chloride. J. W. Gatehouse heated a mixture of ammonium nitrate and manganese dioxide to 180° and obtained nitrogen gas; if the temp. rises over 215°, the manganese nitrate which is formed decomposes, giving off oxygen, nitrogen, and nitrogen peroxide. A. Levy made nitrogen by heating ammonium dichromate: $(NH_4)_2Cr_2O_7=Cr_2O_3+4H_2O+N_2$; and R. de Luna recommended a mixture of potassium dichromate and ammonium chloride, and washing the gas with a soln. of ferrous sulphate. R. Böttger, and C. L. Jackson and J. H. Derby heated a mixture of potassium dichromate, sodium nitrite, ammonium nitrate, and water, and V. Meyer recommended removing oxygen from the product by passing the gas over heated copper; G. von Knorre used an analogous mode of preparation and found that the use of an acidified soln. of a ferrous salt to remove the nitrogen oxides is objectionable because the absorbed nitric oxide is given off again as the nitrogen passes through the soln., and an acidified soln. of potassium permanganate converts the nitric oxide into nitric acid which reacts with the permanganate, giving off oxygen. C. R. C. Tichborne made nitrogen by heating a mixture of ammonium sulphate, sodium nitrite, and an aq. soln. of glycerol; and J. Mai heated a mixture of glycerol, dil. sulphuric acid, and ammonium nitrate to 165°. The reaction is said to commence at 190°, but once started the reaction proceeds at 150°. A few drops of sulphuric acid cause the reaction to proceed more regularly at a lower temp. The gas is said to be evolved regularly, and to be contaminated with oxygen, carbon dioxide, and pyridine bases. S. M. Delépine found that when spongy platinum is boiled with ammonium sulphate and sulphuric acid, nitrogen and sulphur dioxide are formed: $4H_2SO_4+Pt=Pt(SO_4)_2+2SO_2+4H_2O$; and $3Pt(SO_4)_2+2(NH_4)_2SO_4=2N_2+3Pt+8H_2SO_4$. C. W. Geuns observed some nitrogen is formed when a mixture of potassium cyanide and potassium nitrite is detonated by heat. J. Pelouze obtained nitrogen by adding ammonium sulphate to a sat. soln. of nitric oxide in sulphuric acid, and heating the mixture to 160°. According to G. P. Baxter and C. H. Hickey, pure nitrogen can be readily obtained in large quantities by the interaction of nitric or nitrous oxide and ammonia at a high temp. In the case of nitric oxide, the following method is employed. The gas, generated by the action of nitric acid of sp. gr. 1·2 on copper turnings, is led through a wash-bottle containing strong ammonia soln., and afterwards over hot copper gauze or thoroughly platinized asbestos. The nitrogen thus obtained is passed through dil. sulphuric acid, and afterwards over fused potassium hydroxide, through a tower containing glass beads moistened with strong sulphuric acid, and finally through a small tube containing a roll of red-hot copper gauze. The sp. gr. of ammonia soln. for this purpose must not be higher than 0·92. In the case of nitrous oxide, the gas obtained by heating ammonium nitrate is passed over red-hot platinized asbestos, then into a wash-bottle containing strong ammonia soln., and again over heated platinized asbestos. G. von Knorre and K. Arndt obtained nitrogen by oxidizing hydroxylamine with an acid soln. of an alkali nitrate in the presence of cupric sulphate, mercuric chloride, ammonium persulphate, hydrogen dioxide, or vanadium pentoxide; with the last-named catalyst, some nitrous oxide is also produced. E. C. Szarvasy obtained nitrogen in the electrolysis of hydrazine and of its salts; and E. Tiede obtained nitrogen of a high degree of purity by the slow decomposition of azides in vacuo.

Nitrogen is formed in a number of reactions with organic compounds. F. Hoppe-Seyler,[6] L. Liebermann, M. Grüber, M. Pettenkofer and C. Voit, T. Schlösing and A. Müntz, A. Morgen, G. van der Velde, H. B. Gibson, and J. Seegen and J. Nowak, noticed that when fibrin, and some proteids are decomposed, hydrogen sulphide, carbon dioxide, and nitrogen may be formed. The reduction of organic substances in soils to nitrogen gas was indicated by H. Davy in 1813. Confirmatory observations were made by G. J. Mulder, B. E. Dietzell, O. Kellner and T. Yoshii, B. Tacke, and C. Oppenheimer. The reduction of nitrates to nitrogen by bacteria was first reported by U. Gayon and G. Dupetit in 1886, and since that time numerous observations have been made. A. Ambroz, G. Ampola and E. Garino, E. Baur, A. Boutron, K. Brandt, E. Bréal, R. Burri and A. Stutzer, H. R. Christensen, A. Ehrenberg, P. F. Frankland, E. B. Fred, E. Giltay and G. Aberson, A. Gehring, L. Grimbert, and M. Bagros, W. Henneberg, H. Immendorff, H. Jensen, H. Kühl, O. Künnemann, O. Lemmermann, M. Lemoigne, J. Leone, R. Lieske, W. C. C. Pakes and W. H. Jollyman, D. Parlandt, J. Schirokikh, T. Schlösing, S. A. Sewerin, J. Stoklasa, J. Vogel, P. Wagner, R. Warington, O. Wegner, H. Weisenberg, and P. P. Déhérain and L. Maquenne, noted the formation of nitrogen during the reduction of nitrates by bacteria; and E. Buchner and R. Rapp, and B. E. Dietzell, in the reduction of nitrites by yeast. H. Leo found that only a very small liberation of nitrogen occurs during the assimilation of food by flesh-eating organisms. G. Ampola and C. Ulpiani[7] showed that the denitrifying bacteria—*bacterium denitrificans,* etc.—does not attack asparagine, or nitromethane; and with ethyl nitrate the action is slow. The nitrates of lithium, ammonium, sodium, potassium, rubidium, cæsium, beryllium, silver, thorium, yttrium, iron, manganese, and aluminium are not attacked· The more electropositive the metal and the lower its at. wt., the more rapidly does denitrification take place. Carbamide nitrate, which is only slightly dissociated in soln., is slowly attacked, whilst with the nitrates of strychnine, brucine, cocaine, and pilocarpine, which are entirely ionized in soln., denitrification is soon complete. The bacteria do not develop in soln. of metallic chromates, and only to a small extent in soln. of bromates or iodates; chlorates, arsenates, and ferricyanides suffer reduction, but sulphates, phosphates, and molybdates remain unchanged. Calcium nitrate is much less readily attacked than sodium nitrate. M. E. Wollny, and B. Tacke found that in some cases nitrous oxide is formed as well as nitrogen. This was confirmed by M. W. Beyerinck and D. C. J. Minkman, and S. Suzuki. Again, B. Tacke, and A. J. Lebedeff found that nitric oxide is formed by the action of *bacterium hartlebii* on nitrate soln.

§ 6. The Physical Properties of Nitrogen

At ordinary temp., nitrogen is a colourless, odourless, tasteless gas which has no action on vegetable colouring matters. H. Erdmann[1] described liquid nitrogen as a clear, colourless, mobile liquid. J. de Smedt and W. H. Keesom found that the **X-radiograms** of solid nitrogen show that the symmetry of the crystals is less than that of the cubic system. D. Vörlander and W. H. Keesom found that the crystals which form when nitrogen is cooled to —210° are doubly refracting. Contrary to W. Wahl, no isotropic solid state was observed when the solid is cooled down to —253°. The gas is not quite so heavy as air. According to H. V. Regnault, **the weight of a litre** of nitrogen is 1·256167 grms. at 0° and 760 mm.; J. M. Crafts, 1·25647 grms.; P. von Jolly, 1·2574614 grms. at 0°, 760 mm., latitude 45°, and sea-level; Lord Rayleigh, 1·2578731 grms.; and A. Jaquerod and F. L. Perrot, 1·25045 grms. at 0°, and 0·25451 grm. at 1067·4°. M. Paya and E. Moles found 1·25681 grms. for the nitrogen of the air of Madrid—*vide supra*, atmospheric air. Lord Rayleigh obtained a greater value for nitrogen separated from atm. air than from nitrogen prepared from chemical compounds; and Lord Rayleigh and W. Ramsay demonstrated that the result was due to the presence of a heavier gas in atm. nitrogen—*vide* argon. A litre of purified nitrogen was found, by Lord Rayleigh and W. Ramsay, to weigh 1·2505 grms. under standard conditions; and by A. Leduc, 1·2507 grms. E. Moles and J. M. Clavera gave 1·2505 grms. for the nitrogen of air at 0°, 760 mm., and latitude 45°. C. J. T. Hanssen, and J. K. H. Inglis and J. E. Coates made observations on this subject. G. P. Baxter and H. W. Starkweather gave 0·41667, 0·83348, and 1·25036 at 0° and the respective press. 253·33, 506·67, and 760 mm., at sea-level, and latitude 450'. For the **relative density** of atm. nitrogen (air unity), P. L. Dulong and J. J. Berzelius gave 0·968; J. B. A. Dumas and J. B. J. D. Boussingault, 0·972; T. Thomson, 0·9729; H. V. Regnault, 0·97137; J. M. Crafts, 0·97138; A. Leduc, 0·972; and Lord Rayleigh, 0·97209. For purified nitrogen, Lord Rayleigh gave 0·96727; A. Leduc, 0·9671; T. Schlösing, 0·9671; and P. A. Guye, 14·007(H=1·0077). J. K. H. Inglis and J. E. Coates gave 0·8084 at —193·93° and 0·8297 at —195·5°; while E. C. C. Baly and F. G. Donnan gave 0·8010 at —193° and 0·8218 at —198°. The literature was reviewed by M. S. Blanchard and S. F. Pickering. The molecule of nitrogen is diatomic, N_2, and, according to V. Meyer and co-workers, no perceptible dissociation occurs at 1690°.

E. Gerold gave for the **specific gravity,** D, of gaseous nitrogen D=0·0044973 at —195·5° and 741·10 mm. The sp. gr. of liquid nitrogen was found by S. von Wroblewsky to be 0·4552 at —146·6°/4°; 0·5842 at —153·7°/4°; 0·8300 at —193·0°/4°; and 0·8660 at —202·0°/4°. J. Dewar gave 0·8042 at —195·5°, and 0·8792 at —252·5°; J. Drugman and W. Ramsay, 0·7914 at —195·5°; and L. Grunmach, 0·791 at —195·9°. E. C. C. Baly and F. G. Donnan represented the sp. gr., D, of liquid nitrogen, between —184° and —205°, by $D=0·853736-0·00476(T-68)$. They found:

	—205°	—200°	—195°	—190°	—185°
D	0·8537	0·8309	0·8080	0·7851	0·7622

E. Mathias and co-workers have determined the density of liquid nitrogen and of the sat. vap. over the range of temp. between the solidification point and the critical point, and have compared the values with the results already obtained for argon and oxygen. Leaving out the values for the three degrees below the critical temp., the values for the density of nitrogen deviate but very slightly from a straight line, which, however, shows a convex curvature towards the temp. axis at the low temp. Solid nitrogen was found by J. Dewar to have a sp. gr. of 0·8792 at —210·5°, and 1·0265 at —252·5°. E. Rabinowitsch gave 35·4 for the mol. vol.; and the subject was studied by P. N. Pavloff, C. del Fresno, S. Sugden, W. Herz, S. Mokruschin, and C. E. Guye and R. Rudy. I. I. Saslawsky gave 1·12 for the sp. gr., and 10·3 for the at. vol. at absolute zero; and F. Schuster, 10·63 at the b.p. as the constant for calculating the mol. vol. of compounds.

L. Cailletet[2] measured the **compressibility** of nitrogen at 15°, and found the product *pv*, to be:

p .	39·359	49·271	59·462	74·330	114·119	181·985 m.
v .	207·93	162·82	132·86	108·86	76·69	51·27
pv .	8184	8022	7900	8091	8751	9330

E. H. Amagat's results are given in Table X. There is a minimum value for the product *pv* with a press. of 5 m. of mercury. M. W. Travers gave:

p . .	0·76	10	25	35	45	55	65 m.
pv . .	1·0000	0·9963	0·9910	0·9899	0·9895	0·9902	0·9913

The coeff. of compressibility was found by E. H. Amagat to decrease with increasing press.:

Limits of press. .	750–1000	1000–1500	1500–2000	2000–2500	2500–3000 m.
Coefficient . .	0·000407	0·000265	0·000170	0·000122	0·000091

Lord Rayleigh's value for the ratio of *pv* at one atm. press. to its value at half an atm. press. is 1·000015. L. Holborn and J. Otto measured the low temp. isotherms, and found $pv=2{\cdot}46558+1{\cdot}38086p+0{\cdot}8082p^2$ at 400°; $pv=1{\cdot}36682+0{\cdot}36057p+3{\cdot}1510p^2$ at 100°; $pv=1{\cdot}00060-0{\cdot}60716p+3{\cdot}7959p^2$ at 0°; and $pv=0{\cdot}52446-4{\cdot}68594p-24{\cdot}4699p^2$ at —130°. E. H. Amagat showed that the ratio p_0v_0/p_1v_1 is 0·909 between 60 m. and 180 m. press., and Boyle's law is applicable up to 300 m. press. J. A. Liljeström found that for press. below atm. deviations occur. G. P. Baxter and H. W. Starkweather obtained $pv=1{\cdot}00011$ and 1·00028 respectively for press. $\frac{2}{3}$ and $\frac{1}{3}$ atm. when the value for 1 atm. press. is unity. P. de Heen said that if allowance be made for the vol. of the mols., Boyle's law is closely followed by nitrogen. L. B. Smith and R. S. Taylor calculated the compressibility to be 0·000608 at 0°, 0·000216 at 50°, and —0·000071 at 100°; P. Chappius, 0·00043; G. M. Maverick, 0·00044; A. Leduc and P. Sacerdote, 0·00038; Lord Rayleigh, 0·00056; and J. Holborn and J. Otto, 0·000561 at 0°, 0·00023 at 50°, and —0·000360 at 100°. E. Cardoso and T. Levi found for nitrogen at 16° the following values of *K* in the expression $p=Kp_0v_0T/vT_0$:

$p_{atm.}$ . .	1	10	20	40	60	80	95
K . . .	1·0000	0·9971	0·9939	0·9898	0·9887	0·9902	0·9929
K (Amagat) .	1·0000	0·9971	0·9945	0·9907	0·9896	0·9908	0·9930

Observations are also made by H. K. Onnes, T. T. H. Verschoyle, and A. W. Witkowsky. E. P. Bartlett gave for $p_0v_0=1$ at 0° and 1 atm. press., and

p . .	50	100	200	400	600	800	1000
pv/p_0v_0 .	0·9839	0·9840	1·0330	1·1250	1·5211	1·7985	2·0659

E. P. Bartlett concluded that the compressibility of mixtures of hydrogen and nitrogen is not a linear function of its composition. A maximum positive deviation of 1·9 per cent. was observed in a mixture containing 60 per cent. of hydrogen at 200 atm. press. A maximum negative deviation of 0·55 per cent. appears in a mixture containing 25 per cent. of hydrogen at 1000 atm. press.

H. K. Onnes and A. T. van Urk measured the isothermal values of *pv* at 20°, 0°, —23·62°, and intermediate temp. down to —146·32°. P. W. Bridgman found for the press., *p* in kgrms. per sq. cm.; the vol., *v* c.c. per gram of nitrogen, at 68°;

the product pv, where v represents the vol. of nitrogen which under 1 kgrm. press. per c.c. at 0° occupies 1 c.c.; and δv the change in vol. per gram:

p	2500	3000	5000	7000	9000	11,000	13,000	15,000
v	1·356	1·290	1·138	1·056	1·003	0·964	0·933	0·908
pv	4·11	4·68	6·89	8·95	10·94	12·84	14·70	16·50
δv	—0·066	0	0·152	0·234	0·287	0·326	0·357	0·382

TABLE X.—E. H. AMAGAT'S VALUES OF pv FOR NITROGEN.

p Atm.	0°		16·03°		95·45°		109·50°

O. E. Meyer[3] calculated for the **viscosity** of the gas at 10°–20°, $\eta=0{\cdot}000184$; and O. E. Meyer and F. Springmühl, $\eta=0{\cdot}000194$. T. Graham gave $0{\cdot}0_31635$ at 0°; and $0{\cdot}0_31840$ at 20°; and A. von Obermayer gave $0{\cdot}0_31563$ at —21·5°, and $0{\cdot}0_31894$ at 53·5°. For chemical nitrogen, H. Markowsky gave $0{\cdot}0_31674$ at 0°; $0{\cdot}0_31747$ at 15·4°; and $0{\cdot}0_32123$ at 100·08°; and F. Kleint, $0{\cdot}0_31737$ at 13·9°; $0{\cdot}0_32125$ at 99·5°; and $0{\cdot}0_32460$ at 182·7°. For atm. nitrogen, H. Markowsky gave $0{\cdot}0_31695$ at 0°; $0{\cdot}0_31738$ at 14°; and $0{\cdot}0_32464$ at 183·0°. R. S. Edwards and B. Worswick gave $\eta=0{\cdot}0_4944$ at 10° and $0{\cdot}0_31295$ at 100°, and they found 377 for the value of Sutherland's constant; and K. L. Yen, 0·000176480 at 23° and 760 mm. J. H. Jeans gave $\eta=\eta_0(T/273)^{0{\cdot}74}$. A. Bestelmeyer, and C. J. Smith also made observations on this subject. H. Vogel, S. Chapman and W. Hainsworth, M. Hofsäss, and F. Kleint measured the viscosity of mixtures of hydrogen and nitrogen and of oxygen and nitrogen. F. Schuster calculated 846 atm. for the **internal pressure.** L. Grunmach gave $\sigma=8{\cdot}51$ dynes per cm. for the **surface tension** of liquid nitrogen at —195·9°; and for the **specific cohesion,** $a^2=21{\cdot}527$ sq. mm. E. C. C. Baly and F. G. Donnan gave $\sigma=10{\cdot}53$ at —203°, 8·27 at —193°, and 6·16 at —183°; and $a^2=2{\cdot}541$ at —203°, 2·110 at —193°, and 1·663 at —183°. They added that the association factor of the liquid corresponds with a mol. wt. of 37·30; the theoretical value for N_2 being 28. A. T. van Urk studied this subject. W. D. Harkins and L. E. Roberts estimated that the free **surface energies** at —200°, —190°, and —182° are respectively 10·53, 8·27, and 6·57 ergs per sq. cm., or 26·63, 25·87, and 24·61 ergs per area of surface occupied by one mol.; the energy, $3{\cdot}23\times10^{-16}$, $3{\cdot}24\times10^{-16}$, and $3{\cdot}18\times10^{-16}$ ergs per degree per area occupied by one mol.; and each c.c. of liquid holds $18{\cdot}27\times10^{21}$, $17{\cdot}28\times10^{21}$, and and $16{\cdot}49\times10^{21}$ mols. F. de Block represented the surface tension at θ° by the general formula of A. Ferguson, and J. D. van der Waals, namely, $\sigma=\sigma_0(\theta_c-\theta)^{1{\cdot}282}$, where θ_c represents the critical temp., and σ_0 the surface tension at 0°. T. Alty studied the phenomena at the surface of bubbles of nitrogen in water. The coeff. of **diffusion** of nitrogen into oxygen was found by A. von Obermayer to be 0·171 sq. cm. per sec. at 0°, and O. Jackmann,[4] 0·203 sq. cm. per sec. at 12·5° and 755·6 mm. The latter gave for hydrogen into nitrogen, 0·739 sq. cm. per sec. at 12·5° and 755·4 mm. The diffusion of mercury and iodine vapours in nitrogen have been studied by J. M. Mullaly and H. Jacques. J. Stefan found that nitrogen diffuses in water and in alcohol more quickly than carbon dioxide and more slowly than hydrogen. G. Hüfner gave 1·73 sq. cms. per day for the speed of diffusion of nitrogen towards oxygen in aq. soln. at 21·7°. According to M. Berthelot, nitrogen diffuses through quartz glass at 1300°. T. L. Ibbs studied the separation of nitrogen from hydrogen and from carbon dioxide by thermal diffusion. J. Dewar found that nitrogen, at atm. press. and 15°, diffused through rubber 0·01 mm. thick at the rate of 1·38 c.c. per sq. cm. per day. H. A. Daynes also measured the diffusion of nitrogen in rubber. J. Sameshima and K. Fukaya studied the atmolysis of nitrogen; and T. L. Ibbs and L. Underwood, the thermal diffusion of nitrogen and carbon monoxide.

O. Buckendahl[5] found the **velocity of sound** in nitrogen to be 337·30 metres per sec. at 0°; 544·98, at 500°; and 714·83, at 960°. H. B. Dixon and co-workers made analogous observations between 0° and 100°. The observed values at 0° range from 337·3 to 338·7 metres per sec. They gave for the dry gas:

	20°	42°	62°	77°	80°	86°	90°
Metres per sec. .	339·5	352·9	364·1	372·3	373·9	376·9	378·9

They also measured the velocity of sound in mixtures of nitrogen with carbon dioxide, etc.

The **molecular velocity** of nitrogen at 0° was calculated by F. Kleint[6] to be 45,430 cms. per sec.; the mean **free path**, $0{\cdot}0_5949$ cm. at 0° and 760 mm.; the total sectional area of all the mols. in 1 c.c. of gas at 0° and 760 mm., 24,400 sq. cms., and with W. Sutherland's correction, 17,000 sq. cms.; and the **molecular diameter,** 28×10^{-9} cm. For the mol. diameter, F. Exner gave 17×10^{-9} cm.; S. Mokroushin, $1{\cdot}0\times10^{-8}$ to $6{\cdot}7\times10^{-8}$ cm.; H. Sirk, $3{\cdot}1\times10^{-8}$ to $3{\cdot}9\times10^{-8}$ cm.; W. H. Kecsom, $26{\cdot}5\times10^{-9}$ cm.; J. P. Kuenen, $3{\cdot}1\times10^{-8}$ cm.; and P. Walden, $2{\cdot}9\times10^{-8}$ cm.; W. L. Bragg calculated 1·30 A. for the at. diameter, and A. O. Rankine's estimate agrees with this; W. Sutherland, 30×10^{-9} cm.; P. W. Bridgman, $3{\cdot}56\times10^{-8}$ to $3{\cdot}80\times10^{-8}$ cm.; and R. Rühlmann, $34{\cdot}1\times10^{-9}$ cm. J. H. Jeans, E. Brüche, C. Ramsauer, L. L. Nettleton and W. Schütz made some observations on this subject. H. Schmidt gave 1·035 (oxygen unity). C. J. Smith calculated the mean collision area to be $0{\cdot}767\times10^{-15}$ sq. cm.; and R. S. Edwards and B. Worswick, $0{\cdot}633\times10^{-15}$ sq. cm. A. Naumann calculated the mol. cross-section to be 1·88 with that of hydrogen unity; and the mol. radius, 1·307 (hydrogen unity). W. H. Keesom calculated $4{\cdot}77\times10^{-14}$ ergs for the potential energy of the molecules in contact; and for the quadruple moment $3{\cdot}86\times10^{-26}$ C.G.S. units per sq. cm. R. T. Birge discussed the law of force and size of the diatomic molecules; E. Blankenstein, the coeff. of slip, and transfer of momentum; and A. T. van Urk, the cohesion forces of the liquid. R. Gans discussed the structure of the molecules of the gas. For **J. D. van der Waals' constants,** E. Häntzschel gave $b=0{\cdot}001763$. F. Guye and L. Friedrich gave in gram units $a=1660$ to 1770; and $b=1{\cdot}32$ to 1·51; in mol units, $a=1{\cdot}30\times10^{-6}$ to $1{\cdot}39\times10^{-6}$, and $b=37{\cdot}1$ to 39·5; and in terms of the initial vol., $a=0{\cdot}00276$ to 0·00260, and $b=0{\cdot}00166$ to 0·00176. J. J. van Laar calculated $b=0{\cdot}00085$; $\sqrt{a}=0{\cdot}029$; and the valency attraction A, $\sqrt{A}=32$. M. F. Carroll studied the **equation of state.** F. G. Keyes gave for the equation of state $p=2{\cdot}9138(v-\delta)^{-1}T^{-1}-1587(v-0{\cdot}007)\ ^{2}$, where $\log_{10}\delta=0{\cdot}2200-0{\cdot}284v^{-1}$ for E. H. Amagat's data between 100 and 1000 atm., and $p=2{\cdot}9286(v-\delta)^{-1}T^{-1}-1623{\cdot}6(v+0{\cdot}2954)^{-2}$, where $\log_{10}\delta=0{\cdot}18683\quad 0{\cdot}3113v^{-1}$, for L. B. Smith and R. S. Taylor's data over a smaller range of press.

P. W. Bridgman did not obtain good results for his high press. observations with these formulæ. R. Becker applied to E. H. Amagat's results the equation $p=8{\cdot}31\times10^7T(1+40{\cdot}3v^{-1}e^{40{\cdot}3/v})-1{\cdot}26\times10^{12}v^{-2}+384\times10^{17}v^{-7}$, where p is expressed in dynes per sq. cm. and v in c.c. per mol. P. W. Bridgman obtained better results with this equation than with any other tried when applied to his high press. observations. A. T. van Urk found that the curves show a bend in the neighbourhood of the critical temp. and density. R. Bartels and A. Eucken gave the equation of state $pv=nRT(1-Bp)$, where $B=0{\cdot}0022+19600T^{-2}$ for low temp. and small press.; and T. T. H. Verschoyle, $pv=1{\cdot}00049-0{\cdot}0004961p-0{\cdot}0_5334p^2$ for nitrogen at 0°, and for a 50 per cent. mixture with hydrogen $pv=0{\cdot}99969+0{\cdot}0003067p+0{\cdot}0_51147p^2$. W. J. Walker discussed this subject. R. Becker, and J. E. L. Jones and W. R. Cook studied the *intermolecular attraction —vide infra*, electrostriction—and F. G. Keyes and R. S. Taylor, the effect of *molecular aggregation* on the equation of state. M. Trautz and O. Emert, F. Braun, P. Sacerdote, and A. Leduc investigated the application of the partial press. law to mixtures of nitrogen with hydrogen, oxygen, carbon dioxide, and sulphur dioxide. W. Nernst gave 2·6 for the **chemical constant** of nitrogen; J. R. Partington, 0·904; and F. A. Henglein, and A. Langen, —0·05. W. Herz discussed this subject. A. Eucken and co-workers gave —0·11 for the integration constant of the thermodynamic vap. press. equation. The subject was discussed by R. R. S. Cox.

P. von Jolly [7] found the coeff. of **thermal expansion** of nitrogen to be 0·0036677 at one atm. press. between 22° and 98°. A. Jacquerod and F. L. Perrot gave 0·0036643 from 0° to 1067° when the initial press. was 240 mm. and the vol. was kept constant. P. Chappius found the mean coeff. at constant vol. between —20° and 0° to be 0·000367713 (1002 mm.); between 0° and 20°, 0·000367641 (1002 mm.); between 0° and 40°, 0·000367567 (1002 mm.); and between 0° and 100°, 0·0003677466 (1002 mm.). V. and C. Meyer measured the expansion up to 1567°. E. C. C. Baly and W. Ramsay gave 0·003021 at 0·6 mm. (constant vol.) from 13° to 132°, and 0·003290 at 5·3 mm. and 9° to 133°; H. V. Regnault, 0·0036682 at one atm.; P. Chappius, at 1002 mm. press. (constant), 0·0036770 at 0° to 20°; 0·0036750 at 0° to 40°; 0·0036732 at 0° to 100°; and 0·0036778 at 0° to 100° and a constant press. of 1387 mm. F. Henning and W. Heuse gave for the vol. expansion coeff., $\alpha\times10^7=36604+127p_0$; and for the press. expansion coeff., $\beta\times10^7=36604+134p_0$. According to E. H. Amagat, for a constant press., p, between 0° and 16°, the coeff. of expansion, α, is

p .	100	500	1000	1500	2000	2500	3000 atm.
α .	0·00447	0·00310	0·00198	0·00149	0·00127	0·00111	0·00098

between 0° and 99·4°, and 99·4° and 199·5°:

	0° to 99·4°				99·4° to 199·5°			
p . .	200	500	700	900	200	500	700	900
α . .	0·00433	0·00315	0·00256	0·00218	0·00280	0·00235	0·00204	0·00179

At a constant vol., v, between the indicated temp., he also found:

	0° to 16°			0° to 99·4°			99·4° to 199·6°		
p .	100	1000	2800	100	300	500	100	200	400
β .	0·00437	0·00550	0·00424	0·00462	0·00582	0·00596	0·00315	0·00349	0·00364

R. Plank has collated the available press., temp., and vol. data for nitrogen at a low temp. S. von Wroblewsky gave 0·0311 for the coeff. of expansion of the liquid at —153·7°; 0·007536 at —193·0°; and 0·004619 at —202·0°. E. C. C. Baly and F. G. Donnan gave 0·00558 between —184° and —205°. W. Mewes discussed the deviations from Charles's law; and W. Herz, the relation between the internal press. and the thermal expansion.

A. Winkelmann [8] gave for the **thermal conductivity** of nitrogen gas, 0·0000524 cals. per sq. cm. per cm. per degree at 8° ; P. Günther gave 0·00005694 at 0° ; and S. Weber, 0·00005660 ; E. Schreiner gave for the mol. heat conductivity $2·79\times10^{-6}(273/T)^{\frac{1}{2}}$.

A. Crawford [9] attempted, in 1779, to determine the **specific heat** of nitrogen. This constant was found by F. de la Roche and J. E. Bérard to be $c_p=0·2754$; and by H. V. Regnault to be 0·244 between 0° and 200°. A. K. W. Sauerman gave 1·0005 for the ratio c_p/c_v for air. K. Scheel and W. Heuse gave $c_p=0·249$ and $C_p=6·983$ at 20°, and L. Holborn and F. Henning, for a gas with about one per cent. of oxygen :

	0°–200°	0°–400°	0°–600°	0°–800°	0°–1000°	0°–1200°	0°–1400°
Sp. ht. . . .	0·239	0·243	0·246	0·250	0·254	0·258	0·262

L. Holborn and L. Austin gave for the mean sp. ht. at constant press., 0·2419 from 20° to 440° ; 0·2464 from 20° to 630° ; and 0·2497 from 20° to 800°. J. H. Brinkworth found $c_p=0·2468$ at 10° ; 0·2471 at —78° ; and 0·2535 at —183°. P. Vieille gave 4·8 for the molar sp. ht. at constant vol. and at ordinary temp., 6·30 at 3100° ; 7·30 at 3600° ; and 8·1 at 4400° ; while M. Berthelot and P. Vieille gave

	2810°	3191°	3993°	4024°	4309°	4394°
C_v	6·67	7·93	8·43	8·39	9·85	9·60

There is thus a rapid increase in the thermal capacity of the gas, and these results were represented by $C_v=6·7+0·0016(\theta-2800°)$. J. H. Brinkworth obtained $C_v=4·922$ at 10° ; 4·910 at —78° ; and 4·914 at —183°. H. B. Dixon and co-workers gave $C_v=4·775+0·00042T_1$. S. W. Saunders gave for the best representative value, $C_p=6·41+0·000523T$. E. Mallard and H. le Chatelier, C. K. Ingold and E. H. Usherwood, E. Schreiner, and D. Clerk made some observations on this subject. For the liquid, H. Alt gave 0·430 between —208° and —196°. A. Eucken found that the mol. hts. of liquid nitrogen are $C_p=13·15$ at —208·4°, and 13·33 at —200·3°. For the ratio of the two sp. hts., S. Valentiner gave $\gamma=1·45$ at —192° ; A. Cazin, 1·41 at 15° ; O. Buckendahl, 1·405 at 0° ; G. Schweikert, 1·405 at 0° ; F. A. Schulze and A. Rathjcb, 1·412 ; H. B. Dixon and co-workers, 1·406 at 0° ; J. R. Partington and co-workers, 1·405 at 16·7° and 1·4045 at 20° ; and E. Rohlf, 1·389 at 17°. J. H. Brinkworth found 1·4054 at 10° ; 1·4103 at —78° ; and 1·4454 at —183°. W. G. Shilling gave :

$T°$ K. . . .	300°	500°	1000°	1500°	2000°	2500°	3000°
C_v . . .	4·92	4·96	5·20	5·63	6·20	6·77	6·95
C_p . . .	6·92	6·94	7·19	7·62	8·18	8·76	8·94
γ . . .	1·405	1·402	1·382	1·353	1·321	1·293	1·206

and he also gave $C_v=4·93\times10^{0·000002125T^{1·39}}$; as well as $C_v=5·014-0·0_3504T+0·0_68376T^2-0·0_91449T^3$. E. Burlot gave 1·36 at 1890°, and 1·43 at 2096°. E. Schreiner studied the mol. ht. of nitrogen. H. Buff estimated the at. ht. of tervalent nitrogen to be 7·7, and of quinquevalent nitrogen, 4·3 ; while J. Tollinger gave 4·7 for nitrogen in ammonium chloride, and 6·6 in the nitrate. G. Piccardi studied the thermal capacity of the gas.

A. Eucken found that solid nitrogen has a **transition point** at —237·5°, and melts at —209·9°. The mol. hts. of **α-nitrogen** or *nitrogen-II* at —256·5° are $C_p=3·48$, and $C_v=3·46$; and at —239·9°, $C_p=9·63$ and $C_v=9·39$. The mol. hts. of **β-nitrogen** or *nitrogen-I* are $C_p=8·84$ and $C_v=8·61$ at —236° ; and $C_p=11·08$, and $C_v=10·48$ at —212·4°. The value of C_p was calculated from that of C_v by the expression $C_p-C_v=0·0_481TC_p{}^2$—*vide supra*, the crystalline form at low temp.

The **Joule-Thomson effect** with nitrogen has been measured by J. P. Joule and W. Thomson,[10] M. Jakob, and K. Olschewsky. According to J. P. Dalton, for $\theta=0°$ and $p=$one atm.,

p . . .	5	10	15	20	25	30	35	40	45
$\delta\theta$ . . .	1·13°	2·51°	3·88°	5·25°	6·59°	7·92°	9·24°	10·48°	11·69°

The inversion temp. is 243° at 159 atm., and 163° at 30 atm. Observations were also made by H. W. Porter. W. H. Keesom calculated 331° for the inversion temp.

L. Cailletet[11] first observed the **liquefaction** of nitrogen. When the dried and purified gas was compressed at 200 atm. press., and 13° to 29°, and suddenly expanded, he observed the formation of a mist which condensed to small drops and which disappeared in about 3 seconds. This observation was confirmed by M. Berthelot; H. Erdmann also made observations on this subject. Later on, S. von Wroblewsky and K. Olschewsky cooled the gas, under 150 atm. press., to —136° by liquid ethylene; and on expanding the gas slowly, liquefaction occurred. The liquid persisted but a few seconds. K. Olschewsky improved the process. J. P. Kuenen, and J. H. Simons studied the liquefaction of mixtures with oxygen.

S. von Wroblewsky found that at the temp. of liquid oxygen, —186°, compressed nitrogen furnishes large snow-like crystals of the solid; K. Olschewsky could not confirm this observation, but he obtained a crystalline mass of nitrogen by cooling the liquid with evaporating liquid hydrogen. W. Wahl obtained good crystal growths by cooling purified liquid nitrogen. The crystals are dark in all positions between crossed nicols, and they are therefore isotropic; the crystals belong to the cubic system. This result is in harmony with the crystal symmetry of the other members of this family, because although these elements exist in several polymorphic modifications, the forms of phosphorus and arsenic which are stable at the lowest temps. belong to the cubic system, it is also probable of yellow antimony. D. Vorländer and W. H. Keesom did not agree—*vide supra*. The **critical temperature** obtained by K. Olschewsky is —146°, and the **critical pressure,** 33 atm.; J. Dewar obtained respectively —146° and 35°; S. von Wroblewsky, —146·0° to —146·5°, and 33 to 35 atm., and E. Mathias and C. A. Crommelin, —147·13° and 33·49 atm.; and E. Cardoso, —144·6° and 33·65 atm. The subject was studied by W. Herz. E. Sarrau gave 0·004603 for the **critical volume;** and L. Cailletet and P. Hautefeuille, 0·37 for the **critical density;** E. Mathias and C. A. Crommelin, 0·31096. For the latter, S. von Wroblewsky gave 0·44; J. Dewar, 0·3269; E. Mathias and co-workers, 0·31096; and H. Happel, 0·315. J. A. Muller gave 1·285 for the degree of polymerization in the critical state. W. Herz examined the relations of the critical constants. S. F. Pickering gave for the best representative values T_c=126·0° K.; p_c=33·5 atm.; and D_c=0·3110. S. von Wroblewsky found the **vapour pressure** of the liquid to be 32·3 atm. at —146·6°; 20·7 atm. at —153·7°; 1·0 atm. at —193·0°; and 0·105 atm. at —202·0°. E. C. C. Baly found for the vap. press. of chemical and atm. nitrogen:

T° K.	77°	80°	85°	90°	91°
Chem. N	717·0	1013·0	1705·5	2686·0	2916·5
Atm. N	716·0	995·0	1646·0	2581·0	2812·0

C. A. Crommelin represented the vap. press. of liquid nitrogen between —191·88° and —148·85° from p=1·4727 to 20·304 atm., by the expression $\log p=5{\cdot}76381-853{\cdot}522T^{-1}+54372{\cdot}3T^{-2}-1783500T^{-3}$. The vap. press. at the m.p. is 93·5 mm. Observations on the vap. press. of nitrogen up to about one atm. have also been made by K. T. Fischer and H. Alt, G. Holst and L. Hamburger, H. K. Onnes and co-workers, E. C. C. Baly, F. Henning and W. Heuse, P. G. Cath, and H. von Siemens. Higher vap. press. were measured by K. Olschewsky, and C. A. Crommelin, while F. Porter and J. H. Perry gave:

	—182·88°	—177·56°	—174·36°	—166·03°	—159·40°	—154·06°	—151·53°
p atm.	3·631	5·583	7·056	12·193	17·85	23·57	26·75

and these results are represented by $\log_{10} p=-302{\cdot}34T^{-1}+3{\cdot}94127-0{\cdot}00274T+0{\cdot}0_5 1116(T-100{\cdot}5)^3$; and E. Mathias and co-workers gave $\log p=-510{\cdot}64T^{-1}+12{\cdot}831-0{\cdot}12696T+0{\cdot}0008302T^2-0{\cdot}0_5 19975T^3$. H. von Siemens represented the vap. press. of liquid nitrogen by $\log p=-323{\cdot}5T^{-1}+1{\cdot}75\log T-0{\cdot}01292T+5{\cdot}0527$; and of solid nitrogen by $\log p=-345{\cdot}6T^{-1}+1{\cdot}75\log T-0{\cdot}00696T-4{\cdot}7306$. F. A. Henglein gave $\log p=4{\cdot}6222\{(77{\cdot}24/T)^{0{\cdot}89106}+1)\}$—with p in atm. F. Porter and J. H. Perry gave $\log_{10} p=-302{\cdot}34T^{-1}+3{\cdot}94127-0{\cdot}00274T$

$+1{\cdot}116\times10^{-8}(T-100{\cdot}5)^3$. F. Henning gave for the liquid, $\log p=-313{\cdot}694T^{-1}+1{\cdot}75\log T-0{\cdot}011109636T+4{\cdot}487879$, or $\log p=-360{\cdot}500T^{-1}+7{\cdot}679324$; and B. F. Dodge and H. N. Davis, for p atm., $\log_{10}p=-316{\cdot}824T^{-1}+4{\cdot}47582-0{\cdot}0071701T+0{\cdot}0_4294T^2$; or $\log_{10}p=-304{\cdot}494T^{-1}+3{\cdot}93352$. For the vap. press. of mixtures of oxygen and nitrogen, *vide* **1.** 13, 26. V. Fischer studied the vap. press. of mixtures of nitrogen and argon; V. Fischer, and B. F. Dodge and A. K. Dunbar, the vap. press. of mixtures of nitrogen and oxygen—*vide* **1.** 13, 26; and I. R. McHaffie, and E. P. Bartlett, the vap. press. of water in nitrogen compressed over that liquid. V. Kirejeff discussed what he called the cohesive press. of nitrogen. S. von Wroblewsky gave for the **boiling point** of liquid nitrogen —193° at 740 mm.; —201° at 120 mm.; —202·5° at 70 mm.; —204° at 60 mm.; and —206° at 42 mm. J. Dewar made observations on the b.p. of liquid nitrogen. K. Olschewsky gave —194·4° at 760 mm.; L. Grunmach, —195·9° at 749·1 mm.; A. Stock and C. Nielson, —195·35° at 763 mm.; F. Henning and W. Heuse, —195·81° at 760 mm.; E. Mathias and C. A. Crommelin, —195·78°; B. F. Dodge and H. M. Davis, —195·80°; F. Henning, —195·78° to —195·81°; and K. E. Fischer and H. Alt, —195·67° at 760 mm., or —196·176° at 714·5° mm., and —210·52° for the **melting point** at 84 mm. press.; J. Dewar, —210·5°; H. Erdmann, —211°; W. Guertler and M. Pirani, —210°; F. Henning, —209·882°; and A. Eucken, —209·9°. S. von Wroblewsky gave —199° to —203° for the f.p. of the liquid, and K. Olschewsky, —214° at 60 mm. press. W. Herz found that in the equation $\theta_1/\theta_2=T_1/T_2+c(\theta_1-T_1)$, the constant c varies from 0·0007979 to 0·0008695; and θ_1 and θ_2 denote the b.p. of two liquids at a given press., and T_1 and T_2 the b.p. of the same liquids at another press. E. Mathias and C. A. Crommelin gave for the **triple point,** —209·86° and —0·64 atm. press.; and F. Henning, —209·88°, and 92·89 mm. press. For the **heat of vaporization,** J. S. Shearer gave 0·698 Cal. per gram-atom, and 49·83 cals. per gram. D. L. Hammick gave 50·04 cals.; A. Eucken, 1350 cals. per mol; H. Alt gave 1336 cals. per mol, and 47·65 cals. per gram, and he represented the former as a linear function of the temp., $L=1{\cdot}073-0{\cdot}2428\theta$. L. I. Dana gave for the latent heat of vaporization, L cals. per gram for mixtures of nitrogen with p per cent. of oxygen:

p . .	0	10	20	40	60	80	90	100
L . .	47·74	48·37	48·98	50·07	50·83	51·23	51·18	51·01

N. de Kolossowsky studied the relation between the thermal expansion and the heat of vaporization; P Walden, the relation between the capillary constants and the heat of evaporation; and E. Mathias and co-workers, the relation between the latent heat of vaporization and the difference of the sp. hts. of sat. vapour and liquid; and gave $L^2=89{\cdot}9621(T_c-T)-1{\cdot}47242(T_c-T)^2+0{\cdot}003321T^2-0{\cdot}0_43219T^3$, where T_c denotes the critical temp. T. Estreicher found the mol. lowering of the f.p. of nitrogen to be 5·39, and hence computed the **heat of fusion** to be 12·82 Cals. or 53·47 joules. A. Eucken found the heat of fusion of β-nitrogen to be 168·7 cals. per mol; and the **heat of transformation** from α- to β-nitrogen to be 53·8 cals. per mol. E. E. Walker studied the degree of association. From the work of I. Langmuir, A. Eucken, and E. J. B. Willey and E. K. Rideal, the **heat of dissociation** of nitrogen into atoms: $N_2=2N$ is greater than 190,000 cals. and probably of the order 300,000–400,000 cals. per mol. M. Saha believed this value to be much too high. W. Kuhn gave 140 Cals., H. D. Smyth, 145 Cals. K. T. Compton did not succeed in dissociating the molecules thermally—*vide infra,* ionizing potential. R. T. Birge and H. Sponer calculated from the band spectra of N_2, 11·9 volts or 274,000 cals., or 11·4 volts or 263,000 cals. from active nitrogen; and for the $N_2{}^+$-molecule, 9·1 volts or 210,000 cals. from the band spectra. J. C. Thomlinson discussed the heats of formation of various compounds and deduced what he called the **thermochemical equivalent** of nitrogen. K. Bennewitz and F. Simon discussed the energy of the nitrogen molecule. G. N. Lewis and co-workers gave 22·8 for the **entropy** of $\frac{1}{2}N_2$, and also 33·57 for N at 25°; and

B. Bruzs gave 19·0 for the entropy of nitrogen at the m.p., and at 25°. H. C. Urey gave for N_2, 45·59; and E. D. Eastman, 45·6. W. H. Rodebush and co-workers constructed some temp.-entropy diagrams, at 25° and one atm. press. E. Kordes calculated $1·35Q_{\text{cals.}}/T$ for N, 2·7 for N_2, and 5·4 for N_4.

Measurements have been made of the **index of refraction** of nitrogen ranging from J. Koch's[12] $\mu=0·0_33261$ for $\lambda=0·2379\mu$, $\mu=0·0_330937$ for $\lambda=03342\mu$, C. and M. Cuthbertson's $\mu=0·0_33012$ for $\lambda=0·4861\mu$, to H. C. Rentschler's $\mu=0·0_32998$ for $\lambda=0·5461\mu$; and K. Scheel's $\mu=0·0_32945$ for $\lambda=0·7056\mu$. Observations were also made by W. Ramsay and M. W. Travers, M. Croullebois, J. H. Gladstone, E. Stoll, L. Lorenz, and E. Mascart. E. W. Cheney gave $1·0_32985$ for $\lambda=5852$ A.; $1·0_32977$ for $\lambda=6143$ A.; and $1·0_32969$ for $\lambda=6678$ A. C. and M. Cuthbertson gave $\mu=5·0345\times10^{27}/(17095\times10^{27}-n^2)$; and J. Koch preferred the formula:

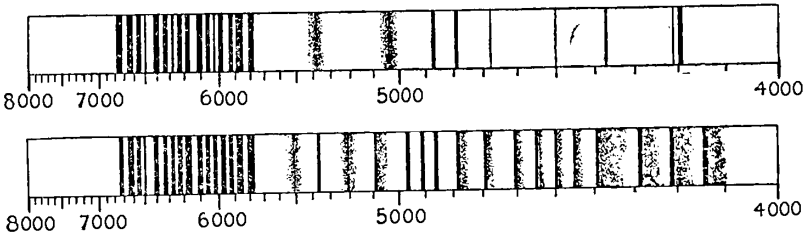
$$\frac{3}{2}\cdot\frac{\mu^2-1}{\mu_2+2}=\frac{3953450\times10^{-8}}{152·294-\lambda^{-2}\times10^{-8}}+\frac{837340\times10^{-8}}{250·65+\lambda^{-2}\times10^{-8}}$$

on the assumption that two kinds of electrons are concerned in the phenomenon. G. D. Liveing and J. Dewar found the index of refraction of liquid nitrogen (containing about 5 per cent. of oxygen) to be 1·2053. E. Gerold studied the optical constants of gaseous nitrogen at its b.p., and found for the gas at 77·97° K. and 752·32 mm. $\mu=1·0010779$ for $\lambda=643·9$; 1·0010847 for $\lambda=546·1$; and 1·0011007, for $\lambda=436·8$; and for the liquid at 77·12° K., and 745·12 mm., $\mu=1·19844$ for $\lambda=656·3$; 1·19876 for $\lambda=579·1$; 1·19918 for $\lambda=546·1$; 1·20042 for $\lambda=435·8$; and 1·20258 for $\lambda=404·7$. J. Cabannes and J. Granier observed the polarization of light laterally diffused in nitrogen. J. H. Gladstone gave for the **specific refractory power,** $(\mu-1)/D=0·293-0·379$; and A. Schrauf, $(\mu^2-1)/D=0·000596$. The subject was studied by C. P. Smyth. J. E. Calthorp, and W. Herz examined the relation between the at. vol. and the index of refraction. C. E. Guye and R. Rudy, and T. H. Havelock studied the electromagnetic rotatory power of nitrogen. J. H. Gladstone gave for the **refraction equivalent,** 4·1–5·1; and R. Löwenherz found for the **atomic refraction** of nitrogen in organic amines and nitrates, 2·870 with the $(\mu^2-1)/(\mu^2+2)$ formula, and 5·38 with the $(\mu-1)$-formula; and for gaseous ter- or quinque-valent nitrogen, both formulæ give too low values. J. W. Brühl calculated 2·21 for the atomic refraction of gaseous nitrogen with the μ^2-formula. G. D. Liveing and J. Dewar gave 8·405 for the mol. refractory power; and 1·205 for D-light, of liquid nitrogen at −190°. R. Frazer observed no change in the refractive index of nitrogen when subjected to magnetic field of 184 gauss. A. Glaser found that nitrogen is oriented in a magnetic field, and hence the atoms and molecules react to light in a manner independent of their orientation. K. von Auwers and co-workers studied the optical properties of nitrogen compounds; and W. Strecker and R. Spitaler, the relation between the index of refraction and structure of organic compounds.

The **electromagnetic rotation of the plane of polarized light** in nitrogen was measured by H. Becquerel,[13] and A. Kundt and W. C. Röntgen. According to L. H. Siertsema, the value for wave-lengths, λ, between $0·423\mu$ and $0·684\mu$, at 14°, and 100 kgrms. per sq. mm. press., is $\omega=0·0001712\lambda^{-1}+0·00004519\lambda^{\ 3}$. C. V. Raman and K. S. Krishnan calculated $0·04\times13^{-10}$ for their constant at 20°. E. Stoll gave for the **dispersion of light** of wave-length $\lambda=4388$ to 9224 A., in nitrogen, $(\mu-1)10^7=2977·27+22·65\lambda^{-2}$, when it is expressed in μ. The **scattering of light** and polarization in nitrogen was studied by Lord Rayleigh. K. R. Ramanathan and N. G. Srinvasan found that the depolarization of light scattered by nitrogen supports the view that the configuration of the outer electrons is like that of the electrons of carbon monoxide.

Quite a number of different spectra of nitrogen have been described. There are the line spectrum, five-band spectra, one of nitrogen at the anode, one of nitrogen at the cathode, one attributed to the oxygen compounds of nitrogen, and one to ammonia. According to J. Trowbridge and T. W. Richards,[14] the so-called channelled spectrum is always obtained by a continuous discharge with no spark-gap or brush discharge in the circuit—the glow in the capillary and about the electrodes has a delicate pink colour. When an air-gap over which the battery discharges in a brush is introduced into the circuit, the glow becomes more violet, and the red band decreases in intensity, and this the more the larger the size of the air-gap—finally the red bands almost wholly disappear and the green and blue bands impart a blue glow to the gas in the capillary. If a condenser is introduced in the circuit, the blue colour changes to a rich bluish-green, and if the condenser discharge is damped by a suitable resistance, the channelled spectrum reappears. The **line spectrum** of nitrogen is produced when a jar-discharge passes through the gas, and when the spectra of metals are examined by allowing the jar-discharge to pass between the metal electrodes in air. The main lines in the green spectrum of nitrogen are shown in Fig. 5. Observations were made by D. Brewster, W. A. Miller, A. J. Angström, D. Alter, J. Plücker, H. W. Dove, V. S. M. van der Willigen, E. Robiquet, G. Kirchhoff, G. G. Stokes, H. C. Dibbits, C. Fievez, A. Ditte, H. Deslandres, G. Séguy, R. Nasini and F. Anderlini, A. Mitscherlich, J. Chautard, W. Huggins, H. F. Brasack, A. Fowler and L. J. Freeman, and A. Schimkoff. J. Formanek gave for the more important lines in the spectrum of nitrogen 5942, and 5933 in the orange-yellow; 5679, 5675, and 5667 in the yellowish-green; 5542, 5535, 5531, 5496, 5480, 5046, 5026, 5017, 5011, 5006, 5003, 4994, and 4988 in the green; 4804, 4789, 4780, 4641, 4629, 4606, and 4601 in the blue; 4446 and 4348 in the indigo; and 4237, 4229, and 3995 in the violet. M. Curie studied the spark spectrum of liquid nitrogen; D. A. Keys and M. S. Home, the striated discharge in mixtures of hydrogen and nitrogen; and B. Trumpy, the breadths and intensities of the lines.

The **band spectrum** of nitrogen in a vacuum tube was observed by J. Plücker, and in the brush discharge of an ordinary electrical machine, by V. S. M. van der Willigen. It is illustrated by Fig. 6. The spectrum was studied by J. Plücker and J. W. Hittorf, H. Nagaoka, J. C. Slater, R. T. Birge and J. J. Hopfield, T. R. Merton and J. G. Pilley, R. Sewig, H. Kirschbaum, L. and E. Bloch, W. Steubing and M. Toussaint, P. Lindau, M. Duffieux, M. Fassbender, H. Sponer, R. T. Birge, G. H. Diecke, R. Mecke, R. S. Mulliken, M. Guillery, E. E. Witmer, A. J. Angström and R. Thalén, M. Hamy, and L. de Boisbaudran. The bands in the red and yellow appear different from those in the blue and violet. Hence, J. Plücker and J. W. Hittorf said that two spectra are really superposed and are really produced by two different sets of mols. By increasing the diameter of the capillary part they obtained a tube which showed only the red and yellow bands; and added:



FIGS. 5 and 6.—The Band, and the Green Spectra of Nitrogen.

> We succeeded in constructing a tube which, when the direct discharge was sent through it, became incandescent with the most brilliant gold-coloured light, which might easily be confounded with the light of highly-ignited vapours of sodium; but with the intercalated jar, the light of the incandescent gas within the same tube had a fine bluish-violet colour. The yellow light when analyzed by the prism gave a beautiful spectrum of shaded bands, extending with decreasing intensity to the blue, the channelled spaces being scarcely

perceptible. The bluish light when examined was resolved by the prism into channelled spaces, extending towards the red; while the former bands almost entirely disappeared. We may transform each colour and its corresponding spectrum into the other *ad libitum.*

G. Salet showed that sodium may be heated in the tube containing the nitrogen without changing the spectrum, and hence inferred that the spectrum is really due to nitrogen and not to an oxide. A. J. Angström and R. Thalén considered that the band spectrum is due to an oxide because with a discharge in air showing the band spectrum, the formation of nitrogen oxide can be demonstrated. A. Schuster, however, considered G. Salet's experiment decisive. The subject has been examined by A. Secchi, H. C. Vogel, A. Schuster, A. Wüllner, A. Cazin, W. Crookes, E. Goldstein, B. Hasselberg, G. D. Liveing and J. Dewar, C. P. Smyth, H. Deslandres, A. T. Sundell, J. S. Ames, E. Warburg, L. Zehnder, J. Trowbridge and T. W. Richards, A. Kalähne, E. S. Ferry, G. A. Hemsalech, G. Berndt, C. Cuthbertson, H. Crew and J. C. Baker, C. C. Hutchins, P. Lewis and A. S. King, A. Hagenbach and H. Konen, J. Stark, P. G. Nutting, A. Hagenbach, J. Schniederjost, E. E. Lawton, R. von der Helm, F. Himstedt and H. von Dechend, etc. M. Toussaint studied the effect of argon, and of iodine on the band spectrum of nitrogen; and W. Schütz, the effect of nitrogen on the spectrum of sodium. M. Duffieux studied the mass of the particles emitting the band spectrum of nitrogen.

J. Plücker and J. W. Hittorf also showed that with a condensed discharge, the vacuum tube glows with a white light. This gives a line spectrum which is identical with that of the spark discharge, but has no relation with the band spectrum just indicated. These observations were confirmed by A. Wüllner, E. Reitlinger and M. Kuhn, O. Schenk, and L. de Boisbaudran. The line spectrum has been also examined by A. Secchi, H. C. Vogel, G. Salet, A. Cazin, O. Neovius, J. Trowbridge and T. W. Richards, A. Schultz, W. Wien, H. Deslandres, H. Moissan and H. Deslandres, G. A. Hemsalech, F. Exner and E. Haschek, G. Berndt, P. Hermesdorf, J. Stark, P. W. Merrill and co-workers, P. G. Nutting, and A. Hagenbach and H. Konen. M. Curie studied the spark discharge in liquid nitrogen. G. M. J. McKay observed no evidence of spectral lines from nitrogen heated to 3200° K., and he attributed the spectrum obtained by A. S. King, and G. A. Hemsalech from the heated gas to a chemical action of some kind. The **arc spectrum** has been examined by B. Walter, A. Hagenbach, A. H. Pfund, K. T. Crompton and O. S. Duffendack, R. A. Wolfe and O. S. Duffendack, A. S. King, T. R. Merton and J. G. Pilley, K. T. Compton, and C. T. Kwei; the **ultra-red spectrum,** by E. R. Drew, J. C. McLennan and co-workers, A. H. Pfund, J. W. Ellis, W. W. Coblentz, E. O. Salant, and R. von der Helm; the **ultra-violet spectrum,** by H. Deslandres, H. Kreusler, G. Berndt, L. Ciechomsky, P. Baccei, F. Exner and E. Haschek, J. J. Hopfield and S. W. Leifson, S. W. Leifson, I. S. Bowen and S. B. Ingram, I. S. Bowen and R. A. Millikan, O. Oldenburg, A. W. Wright and E. S. Downs, V. Schumann, A. Dauvillier, and J. Schneiderjost; the **electrodeless tube spectrum,** by P. D. Foote and A. E. Ruark, and P. Lewis; the **flame spectrum,** by J. Schneiderjost, and C. de Watteville; the **canal ray spectrum,** by A. Schultz, E. Goldstein, J. Stark and co-workers, W. Hermann, E. E. Lawton, R. Pohl, and V. Berglund; and the **absorption spectrum,** by E. Luck, A. Kundt, P. M. Garibaldi, L. Cailletet, J. N. Lockyer, J. Moser, J. L. Schönn, F. Holweck, B. Hasselberg, J. L. Soret, W. J. Russell and W. Lapraik, W. N. Hartley, R. T. Birge, P. Hautefeuille and J. Chappius, G. H. Dieke, G. D. Liveing and J. Dewar, and P. Baccei. F. C. Brickwedde and W. A. MacNair found no absorption with liquid nitrogen between wave-lengths 2000 A. and 6500 A. M. Fassbender studied the **negative band-spectrum**; V. S. M. van der Willigen found that the **spectrum of the negative glow** in a nitrogen tube is not usually shown in other parts of the tube. It was mapped by A. J. Angström and R. Thalén. It is a channelled spectrum fading away towards the blue. The bands partially overlap some of the bands of the spectrum of the positive discharge. The bands of the spectrum of the negative glow belong to a spectrum distinct from the ordinary spectrum of the positive discharge although traces of the former may occur in the latter. If the press. is much reduced, the negative glow gradually extends throughout the whole tube. This subject has been examined by F. Brasack, A. Schultz, A. Schuster, P. Lewis, and H. Deslandres, and the spectrum of the after-glow and the fluorescence in a vacuum tube, by P. Lewis, O. Oldenberg, and K. von Mosengeil. O. Oldenberg studied the fluorescence of nitrogen in the ultra-violet; J. C. McLennan and co-workers, G. Cario, and D. A. Keys, the phosphorescence spectrum of solid nitrogen bombarded by electrons—the 5577 line is due to oxygen, *vide supra*, air; B. Reismann, and L. Vegard, the cathode ray spectrum of nitrogen in a vacuum tube. O. Oldenberg found that the fluorescence produced in nitrogen by short-wave, ultra-violet light has a spectrum showing bands due to neutral and ionized molecules. H. O. Kneser studied the excitation of the bands by electron collisions.

Lord Rayleigh, R. C. Johnson, and W. Steubing and M. Toussaint studied the effect of the *inert gases* on the band spectrum of nitrogen. A. Wüllner described the changes which occur in the spectrum of nitrogen as the *pressure* in the tube is gradually increased. S. Datta studied the effect of bromine on the spectrum of nitrogen; W. H. B. Cameron, the effect of neon; D. A. Keys and M. S. Home, the effect of hydrogen; and C. Füchtbauer and G. Joos, the broadening of the spectral lines by other gases. The effect of press. has been also examined by E. Villari, E. Goldstein, J. Huddleston, A. Cazin, W. Crookes, T. R. Merton, and A. Zehden; and the effect of a low *temperature*, by K. R. Koch, J. C. McLennan and G. M. Shrum, M. Cantone, A. Hagenbach, and J. P. Donaghey. According to H. Erdmann and co-workers, the reddish-violet colour of the ordinary discharge tube, showing the band spectrum, becomes greenish-yellow when cooled with liquid nitrogen, and then it shows the line spectrum. L. Vegard and co-workers, and J. C. McLennan and co-workers, studied the spectrum of the light emitted by bombarding solid nitrogen, and mixtures of nitrogen and neon, with high velocity cathode rays, at the temp. of liquid helium, D. C. Duncan, and H. O. Kneser, the spectrum produced by electronic impacts; H. Kerschbaum, the duration of the light emitted by arc and spark. The effect of a *magnetic field*—the *Zeeman effect*—was examined by W. Schütz, J. Chautard, H. Krefft, G. Berndt, W. Wien, L. Grebe and A. Bachem, J. E. Purvis, W. Steubing, and N. Vaccaro; of an *electric field*, by U. Yoshida, and S. Datta; the *Doppler effect*, by J. Stark, H. Rau, H. Krefft, and W. Hermann; J. A. Schwindler, the effect of the *potential* and *frequency* of the spark; and L. Grebe and A. Bachem, the *gravitational displacement* of the $\lambda=3883$ A. line of the solar spectrum. The spectra of the *nitrogen oxy-compounds* have been described by G. L. Ciamician, G. Scheibe, E. Demarçay, L. Bell, W. N. Hartley, P. Lewis, H. O. Kneser, A. Dufour, and E. Warburg and G. Leithäuser; and the spectrum of *ammonia*, by A. Schuster, K. B. Hofmann, J. L. Schönn, L. de Boisbaudran, H. O. Kneser, G. Magnanini, L. Zehnder, R. Mecke and P. Lindau, W. N. Hartley, P. Lewis, J. Trowbridge, and W. H. Bair; of *amines*, by H. Ley and F. Volbert, and G. Scheibe; while W. W. Coblentz, E. O. Salant, J. W. Ellis, E. Hulthèn and S. Nakamura, W. Jevons, K. von Auwers and R. Kraul studied the spectrochemistry of the nitrogen compounds.

Regularities in the spectral lines have been discussed by A. Kratzer, R. A. Millikan and I. S. Bowen, I. S. Bowen, R. Rudy, B. Rosen, H. Sponer, C. C. Kiess, F. Croze, F. Croze and J. Gilles, L. de Boisbaudran, G. J. Stoney, D. Gernez, J. Stark and O. Hardtke, H. Deslandres, and H. Deslandres and A. Kannapell. J. J. Hopfield, A. Fowler, S. Datta, identified **series spectra.** This makes it appear as if the ordinary line spectrum is the spark spectrum of N^+; while A. Fowler has suggested that the so-called enhanced lines, obtained by using a powerful stimulus, may represent a second stage in the ionization. E. Hulthèn and G. Johansson, K. Beckert and M. A. Catalan, C. C. Kiess,

M. Holweck, and P. Lindau studied the structure of the nitrogen bands. E. Condon, and R. Mecke discussed the distribution of energy in the band spectrum. M. Duffieux estimated the masses of the particles that produce the nitrogen spectrum.

F. Holweck,[15] and A. Dauvillier studied the K-series of the **X-ray spectrum**; and C. G. Barkla, the J-series. The **scattering of X-rays** in nitrogen has been studied by J. A. Crowther, J. S. Townsend, and C. W. Hewlett; the absorption of X-rays, by T. E. Aurén, and F. Holweck, and the diffraction of X-rays in liquid nitrogen, by W. H. Keesom and J. de Smedt; and J. M. Nuttall and E. J. Williams, the ranges of the β-rays in nitrogen; G. P. Harnwell, H. K. Erikson, H. Kallmann and M. A. Bredig, J. W. Broxon, S. P. McCallum and C. M. Focken, W. W. Merrymon, and I. Langmuir and H. A. Jones investigated the **ionization** of nitrogen; T. L. R. Ayres, and K. T. Compton and C. C. van Voorhis, the ionization by collision; P. M. S. Blackett, W. P. Jesse, R. W. Gurney, ionization by α-particles, and by slow electrons; H. Sponer and co-workers, the **heat of ionization,** $N_2 \rightarrow N^{\cdot}_2$. H. D. Smyth, A. L. Hughes, K. T. Compton and C. C. van Voorhis, and T. R. Hogness and E. G. Lunn, studied the ionization of nitrogen by electronic impact, and the results show that the ordinary ionizing potential at 16·9 volts corresponds with the production of singly charged mol. ions, $N^{\cdot}_2$; and singly and doubly charged atomic ions, $N^{\cdot\cdot}$, $N^{\cdot}$, at 27·7 volts. T. R. Hogness and E. G. Lunn, and R. T. Birge discussed the energy levels of the nitrogen mol. T. L. R. Ayres studied the collision frequency of electrons and molecules; and V. H. Bailey, the attachment of electrons to the molecules of nitrogen. The **velocity of the ions** in an electric field with a potential difference of one volt per cm. was found by J. Franck to be 1·27 cms. per sec. for the positive ions and 1·84 to 120·4 cms. per sec. for the negative ions from polonium at 15° and 760 mm. W. B. Haines obtained 370–500 cms. per sec.; H. B. Wahlin, 18,000 cms. per sec.; and L. B. Loeb, about 10,000 cms. per sec. L. Meitner and K. Freitag studied the tracks of the α-particles in nitrogen; J. M. Nuttall and E. J. Williams, the tracks and ranges of the β-rays in nitrogen; P. Auger, the photo-electrons; O. Laporte, the mobilities of ions in nitrogen; and M. C. Johnson, the velocities of the ions in stellar atmospheres under the influence of radiation pressure. For the **diffusion coefficient of ions** in nitrogen E. Salles obtained 0·0295 sq. cm. per sec. for the positive ions, and 0·041 for the negative ions. H. F. Mayer, and R. B. Brode studied the absorption of slow moving electrons by nitrogen mols. S. P. McCallum and C. M. Focken measured the rate of increase of current due to ionization when the electrons are produced by a heated filament and by ultra-violet light; and they compared the effect of ionization by collision with that due to radiation. J. S. Townsend and V. A. Bailey estimated that when an electron moving with a velocity of the order of 10^8 cms. per sec. collides with a mol. of nitrogen, it loses more than 1 per cent. of its energy. C. Ramsauer studied the effective cross-sectional area in collision between the mols. of nitrogen and electrons. R. B. Brode studied the mean free path of the electrons; E. Brüche, the area offered by nitrogen molecules to slow electrons; W. Harries, the loss of energy by the collision of slow electrons with nitrogen molecules; and G. P. Harnwell, inelastic collisions in ionized mixtures of nitrogen and the rare gases.

O. S. Duffendack and D. C. Duncan studied the excitation of the spectra of nitrogen by electronic impacts; and V. Kondratéeff found that a voltage of 32 ± 2 is necessary to make the band spectrum of nitrogen appear, although atomic lines made their appearance first. The nitrogen molecule can break down in one action into excited atoms $N_2 \rightarrow N' + N'$, or $N_2 = N' + N^{\cdot} + \Theta$. B. Davis and F. S. Goucher showed that the ionization at about 7·5 volts is not really the **ionizing potential,** but rather represents the least energy an electron must have in order that it may excite radiation by the bombarded mol.; they gave about 18 volts for the ionizing potential. H. D. Smyth obtained a similar result, and

E. Brandt obtained 17·75 volts, and higher ionization stages at 25·41 volts and 30·72 volts—C. B. Bazzoni and A. T. Waldie confirmed these results—B. Davis gave 17 and 29·9 volts; G. B. Kistiakowsky, 17 volts; G. Stead and B. S. Gossling, 17·2 volts; and R. A. Morton and R. W. Riding, 17·01 volts. L. and E. Bloch found that the negative band spectrum of nitrogen has an ionizing potential of 21·5 volts, and the positive band spectrum of 12 volts. E. E. Witmer gave 18 volts for the critical potential of the negative band spectrum of nitrogen. G. Kistiakowsky found ionization potentials for nitrogen on an iron catalyst at 11·1, 13·0, 16·0, and 17·1 volts. K. T. Compton, A. S. Levesley, and A. L. Hughes and A. A. Dixon made observations on this subject. A. E. Ruark and co-workers gave 16·9 volts for the ionizing potential of nitrogen, and 8·18 volts for the inelastic collision potential; O. S. Duffendack gave 16·2 volts; C. A. Mackay, 16·3 volts. P. E. Boucher gave for the ionizing potential 15·8 volts; for the **resonance potential,** 8·4 volts; and for the potentials at which radiation is prominent, 8·4–15·8 volts. F. L. Mohler and P. D. Foote gave 8·18 volts for the resonance potential and 16·9 volts for the ionization potential. The resonance potential corresponds with the nitrogen doublet at λ=1492·2 A., and 1494·8 A., whilst the ionizing potential corresponds with the first term of the spectral series converging at λ=730 A. P. E. Boucher, R. Rudy, B. Rosen, H. E. Krefft, J. Franck, and C. G. Found made observations on this subject. N. Perrakis worked out a relation between the ionizing potential and the critical constants. B. Davis studied the relation between the critical potentials and the indices of refraction.

The **discharge tension** of the current required for spherical electrodes was found by A. Orgler[16] with nitrogen at different press., p, and with spark gaps 0·50 cm. and 0·10 cm., to be

p . . .	750	650	450	250	100	60	40 mm.
Kilovolts (0·5) .	18·13	16·20	12·08	7·617	3·840	2·691	2·010
Kilovolts (0·1) .	4·890	4·398	3·366	2·235	1·218	—	—

H. Kerschbaum studied the duration of luminous cathode rays in nitrogen. Observations were also made by R. J. Strutt, W. Wien, and H. E. Hurst. Observations on the point discharge were made by E. Warburg and F. R. Gorton. M. Pirani examined the effects of minute traces of impurity on the point discharge in nitrogen; K. G. Emeléus, the distribution of the potential in the glow discharge in nitrogen; T. Terada and U. Nakaya, the structure and form of the sparks; C. Eckart and co-workers, the low-voltage arc oscilliations; and A. Günther-Schulze, and O. W. Richardson and R. Chaudhuri studied the potential gradient. According to J. Franck and G. Hertz, an electron formed in the neighbourhood of a point cathode in a pure gas can lead to a strong ionization, and consequent variation in the current, which, however, is irregular in occurrence, owing to the infrequency of the phenomenon. On the other hand, the presence of minute amounts of electronegative substances, such as oxygen, oxides of nitrogen, or water, causes an increase in the current, owing to the production of electrons at the cathode. Such a gaseous mixture, however, does not behave in a stable manner, the phenomena being complicated by the occurrence of slow chemical changes, which cause gradual alteration in the strength of the current, in accordance with the nature of the chemical processes. With a pure gas, the current rises initially, owing to the liberation of inherent impurities by the heat, but falls when the maximum of impurity has been passed. In an impure gas, on the other hand, more strongly electronegative products (such as nitric oxide) may be readily formed, thus causing a decrease in the current, which subsequently rises after partial or complete absorption of the impurities by the electrodes. M. Pirani found that the maximum current strength depends on the oxygen content. The time-current curves for mixtures containing oxygen, in contrast to those for pure nitrogen, exhibit a steep rise after a time. Obviously, the oxygen is gradually consumed, possibly by formation of nitric oxide, which is removed by the molybdenum or other oxidizable part of the apparatus. The removal is not, however, quantitative, and there remain minute traces of oxygen which raise the current strength above the normal value. The mixture in which the greatest rise was observed contained about 5×10^{-4} per cent. The appearance of the point discharge is more considerably modified by water vap. than by oxygen. The time-current curves, in contrast to those of mixtures containing oxygen, exhibit a definite and less defined minimum which gradually disappears with increasing water-vapour content, and, in particular, show a gradually rising branch, the current values for which with mixtures poor in aq. vap. lie above those for pure nitrogen, and appear to lead asymptotically to a final value. The processes on which these curves depend are obviously very complicated, owing to the dissociation of water vapour. With slight modifications, the experiments can be extended to the rare gases; the sensitiveness is greater in these cases, but the phenomena are generally similar. The presence of hydrogen in nitrogen to the extent of 0·1 per cent. or more can be detected with certainty by means of the time-current curves, but the slight elasticity of the hydrogen molecules renders the method less sensitive. O. Hammershaimb and P. Mercier, and R. H. George and K. A. Oplinger studied the sparking potential of nitrogen; and H. Stücklein, the effect of water on the sparking potential. W. Clarkson studied the flashing of argon-nitrogen discharge tubes; H. Fischer, the discharge with Tesla currents. The potential difference of the cathode for the glow discharge with different metals in nitrogen was measured by K. Rottgardt, R. Seeliger, O. S. Duffendack, R. Holm, W. Heuse, E. Warburg, and C. A. Skinner. P. D. Foote and A. E. Ruark studied the electrodeless discharge in nitrogen. G. Holst, and E. Blechsmidt studied cathodic disintegration in nitrogen.

The **dielectric constant** of nitrogen at one atm. press., and 0°, was found by H. Rohmann[17] to be 1·000606; E. Bodareu gave 1·000587 at ordinary press., and for press. at which the density is D, $(K-1)10^7=1954(K+2)D$; and K. Tangl gave for 20°, 1·00581 at one atm. press.; 1·01086 at 20 atm.; and 1·05498 at 100 atm.; and E. C. Fritts, 1·000555. C. T. Zahn found the dielectric constant, ϵ, of nitrogen to be $(\epsilon-1)10^6=1898$ at $-88·9°$; 792 at $-75·2°$; 581 at 0°; and 283 at 289·1°; and the results can be represented by P. Debye's expression $(\epsilon-1)^vT=0·000580T$, where v is the sp. vol. per c.c. of an ideal gas at n.p. θ. L. Ebert and W. H. Keesom gave 1·472 at $-209·1°$, and 1·440 at $-196·5°$ for liquid nitrogen; and 1·45 to 1·46 for solid nitrogen at $-213°$. W. Herz, K. Wolf, and G. L. Addenbrooke studied the connection between the dielectric constant and other physical properties. J. H. Jones discussed the quantum theory of dielectrics; and G. Jung, the orientation of the molecules in dielectrics. W. Kliefoth observed the **electrostriction** or contraction in vol. which occurs when an cxternal electric force is applied to the gas; this indicates that the attraction between the molecules is of electrical origin.

M. Faraday said that nitrogen "appears to be neither magnetic nor diamagnetic." F. Zantedischi discussed this subject. The **magnetic susceptibility** found by G. Quincke at 16° was $+0·001\times10^{-6}$ vol. unit at one atm. press., and $+0·04\times10^{-6}$ at 40 atm. press. T. Soné gave $-0·00033\times10^{-6}$ vol. unit at 20°, and $-0·265\times10^{-6}$ mass unit for chemically pure nitrogen; and $-0·000360\times10^{-6}$ vol. unit and $-0·452\times10^{-6}$ mass unit for atm. nitrogen. F. J. von Wisniewsky gave $-4·91\times19^{-10}$ mass units. L. G. Hector gave $-49·1\times10^{-7}$ for the vol. susceptibility of nitrogen at 20° and 760 mm.; P. Pascal calculated for combined nitrogen $-55·5\times10^{-7}$. The subject was studied by G. W. Hammar. According to A. Glaser, as the press. of the nitrogen is diminished, the susceptibility at first decreased in proportion; but this ceased when a definite press. was attained, and thereafter, the rate of the diminution of the susceptibility decreased greatly, so that at very low press. the susceptibility is three times as great as it could have been if the original rate of diminution had been maintained throughout. He suggested that at low press., the distancc between the mols. is such that there is time between the collisions for the mols. to become oriented with respect to the field. At higher press., the collisions are constantly destroying any tendency to orientation, so that all the mols. are practically unoriented. G. Breit found the susceptibility to be proportional to the press. if that be sufficiently high or sufficiently low, but there is an intermediate region where the relation is non-linear. B. H. Wilsdon calculated values for the magnetic constants. N. C. Little observed a fall in temp. when nitrogen is excited between the poles of an electromagnet.

§ 7. The Solubility of Nitrogen

J. Priestley[1] observed that nitrogen is given off when water freezes, and hence inferred that water is converted into nitrogen during the operation, or else it contains more nitrogen in soln. than is usually suspected, but H. Davy showed that the gas is only in soln. as common air. Nitrogen is soluble in water. N. T. de Saussure said that one vol. of water at 18° dissolves 0·0417 vol. of nitrogen, 0·0147 vol. at 15·5° according to W. Henry; and, according to J. Dalton, 0·0156 vol. at ordinary temp. Observations were also made by R. Bunsen, W. E. Adeney and H. G. Becker, K. Angström, J. H. Coste, C. Jäger, B. Schulz, T. E. Thorpe and J. W. Rodger, E. B. Truman, M. Trautz and H. Henning, F. Weigert, C. J. J. Fox, K. Drucker and E. Moles, C. Müller, A. Findlay and H. J. M. Creighton, G. Just, L. Braun, G. von Hüfner, W. Dittmar, A. Hamberg, J. H. Hildebrand, O. Petterson and K. Sodén, and C. Bohr and J. Bock. A selection from the results of L. W. Winkler is given in Table XI, where the **absorption coefficient,** β, represents the vol. of gas, reduced to 0° and 760 mm., which is absorbed by one vol. of liquid when the press. of the gas, without the partial press. of the liquid, amounts to 760 mm.; the **solubility,** S, represents the vol. of gas reduced to 0° and 760 mm., absorbed by one vol. of the liquid when the barometer indicates 760 mm.; and, q, the weight of gas in grams taken up by 100 grms. of liquid at the indicated temp., and when the partial press. of the gas plus the vap. press. of the liquid totals 760 mm. H. E. Roscoe and J. Lunt said that a litre of water sat. with air contains

TABLE XI.—THE SOLUBILITY OF NITROGEN IN WATER.

Temp.	β	S	q	Temp.	β	S	q
0°	0·02348	0·02334	0·00239	50°	0·0109	0·00955	0·00121

45°	0·01129	0·01023	0·00128	100°	0·00947	0·0000	0·00000

15·47 c.c. of nitrogen, and 7·87 c.c. of oxygen at 0°; at 15°, 13·83 c.c., and 7·09 c.c. of oxygen; at 20°, 12·76 c.c., and 6·44 c.c. of oxygen; and at 25°, 11·78 c.c., and 5·91 c.c. of oxygen. Observations were also made by E. Ruppin, G. C. and M. C. Whipple, A. Hamberg, W. Dittmar, and O. Pettersson and K. Sodén—*vide* air. R. Bunsen represented the coeff. of absorption, at $\theta°$, by $\beta=0{\cdot}020346-0{\cdot}00053887\theta+0{\cdot}000011156\theta^2$. The solubility of nitrogen in *sea-water* was measured by C. J. J. Fox, W. Dittmar, J. H. Coste, A. Hamberg, and H. Tornoë. L. Cassuto measured the effect of pressure, *p* in metres of mercury, on the solubility coeff. of nitrogen in water, and found:

19·4°	*p*	0·8910	1·2488	2·9074	4·5958	6·2767	7·5815	8·1074
	S	0·01617	0·01611	0·01585	0·01554	0·01515	0·01487	0·01473
24·9°	*p*	0·8977	1·15573	2·5171	4·0947	5·0529	7·0333	8·1846
	S	0·01498	0·01487	0·01478	0·01440	0·01429	0·01382	0·01369

K. S. Wyatt found that an aq. soln. of nitrogen, saturated at a press. exceeding 100 atm. at ordinary temp., could be brought to atm. press. without the immediate formation of bubbles in the body of the liquid; and F. B. Kenrick and co-workers studied the supersaturation of water with nitrogen. W. E. Adeney and H. G. Becker measured the *rate of solution* of nitrogen in water and found that $dw/dt=a-bw$, where w represents the total quantity of gas in soln. at any moment; t, the time; and a and b are constants depending on the size of the apparatus. The rate of solution depends on the humidity of the gas, being greater with dry than with moist air. J. Metschel discussed the supersaturation of nitrogen in water. I. R. McHafie studied the conc. of water in the gas phase with air in equilibrium with water. F. Garelli and E. Monath observed no appreciable lowering of the f.p. of stannous chloride by the dissolution of nitrogen.

E. Erdmann and F. Bedford found that liquid *oxygen* absorbs nitrogen energetically from the atm. At −191·5°, 14·880 grms. of liquid oxygen absorb 5–6 litres of gaseous nitrogen at the same time almost doubling its vol. A. Stock made some observations on this subject—*vide* the vap. press. of liquid air. For the coeff. of absorption of nitrogen by *sulphuric acid*, C. Bohr found between 20·9° and 21·5°:

H_2SO_4	0	4·9	10·7	20·3	29·6	34·3	35·8
β	0·0156	0·0091	0·0066	0·0049	0·0051	0·0100	0·0129

Measurements were also made by A. Christoff. L. Braun gave for the coeff. of absorption of nitrogen in aq. soln. of *sodium chloride* and of *barium chloride*:

	0°	5°	10°	15°	20°	25°
NaCl	0·6 per cent.	0·0200	0·0185	0·0164	0·0148	0·0130
	11·73 ,, ,,	0·0102	0·0093	0·0081	0·0066	0·0047
$BaCl_2$	3·33 ,, ,,	0·0183	0·0168	0·0150	0·0135	0·0119
	13·83 ,, ,,	0·0127	0·0117	0·0104	0·0092	0·0078

J. H. Coste and E. R. Andrews measured the solubility of nitrogen in soln. of sodium, *potassium and ammonium chlorides;* and A. T. Larsen and C. A. Black, in liquid *ammonia*. N. T. de Saussure said that 100 vols. of either water or alcohol of sp. gr. 0·84 dissolve 4·2 vols. of nitrogen at 18° and 760 mm. The solubility of nitrogen is greater in *alcohol* than in water. R. Bunsen gave for the absorption coeff.:

	0°	5°	10°	15°	20°	24°
β	0·1263	0·1244	0·1228	0·1214	0·1204	0·1198

L. Carius gave $\beta=0{\cdot}126338-0{\cdot}000418\theta+0{\cdot}0000060\theta^2$. Observations were also made by G. Just, and S. Gniewasz and A. Walfisz. J. Metschel discussed the supersaturation of soln. in alcohol. For the solubility expressed as the ratio of the vol. of gas absorbed at any given temp. and press. to the vol. of the absorbing liquid, or the vol. of gas absorbed per unit vol. of solvent, G. Just found at 20° and 25°

respectively for water, 0·01705 and 0·01634; *methyl alcohol*, 0·1348 and 0·1415; *ethyl alcohol* (99 per cent.), 0·1400 and 0·1432; *amyl alcohol*, 0·1208 and 0·1225; *isobutyl alcohol*, 0·1701 and 0·1734. J. W. Döbereiner said that ether absorbs 0·15 vol. of nitrogen, and A. Christoff found the solubility of nitrogen in *ether* at 0° is 0·2580, and at 10°, 0·2561. G. Just gave for the solubility at 20° and 25°, respectively, *aniline*, 0·02992 and 0·03074; *sulphur dioxide*, 0·05290 and 0·05860; *nitrobenzene*, 0·06082 and 0·06255; *benzene*, 0·1114 and 0·1159; *acetic acid*, 0·1172 and 0·1190; *xylene*, 0·1185 and 0·1217; *toluene*, 0·1186 and 0·1238; *chloroform*, 0·1282 and 0·1348; *acetone*, 0·1383 and 0·1460; *amyl acetate*, 0·1512 and 0·1542; and *ethyl acetate*, 0·1678 and 0·1727. J. H. Hildebrand expressing the solubility in terms of the molar fraction $N\times10^4$ when the press. p is 1 atm., at 20°, found for the solubility of nitrogen in xylene, 6·1; ethyl acetate, 6·8; toluene, 5·3; chloroform, 4·3; benzene, 4·1; acetone, 4·2; ethyl alcohol, 3·3; nitrobenzene, 2·6; methyl alcohol, 2·2; aniline, 1·1; *carbon disulphide*, 1·3; and water, 0·13. G. Tammann also measured the solubility of nitrogen in ethyl, methyl, and amyl alcohols, benzene, aniline, carbon disulphide, *isobutyl, and amyl acetates*, ethylacetate, benzene, toluene, xylene, nitrobenzene, acetone, acetic acid, and chloroform. S. Gniewasz and A. Walfisz gave for the absorption coeff. of nitrogen in *petroleum* at 10°, 0·135; and at 20°, 0·117. L. Braun gave for 3·82 per cent. aq. soln. of *propionic acid*, 0·0209 at 5° and 0·0137 at 25°; and for 11·22 per cent. soln., 0·0195 at 5° and 0·0130 at 25°. K. Drucker and E. Moles gave 0·1640 for the solubility of nitrogen in *isobutyric acid* at 25·05° and 388·3 mm., and 0·1656 at 832·2 mm.; for 37·5 per cent. isobutyric acid at 23·02° and 246·2 mm., 0·0393 and at 867·3 mm. press., 0·0401; and at 29·02° and 231 mm., 0·0373, and 720 mm. press., 0·0386. L. Braun gave for 2·28 per cent. aq. soln. of *urea*, 0·0199 at 5°, and 0·0139 at 25°; and for 15·65 per cent. soln., 0·0175 at 5°, and 0·0130 at 25°. C. Bohr said that *blood* absorbs relatively more nitrogen than water. A. Findlay and H. J. M. Creighton found that the solubility of nitrogen in blood, or in *serum*, is less than in water. C. Himly said that one vol. of *caoutchouc* absorbs 5 vols. of nitrogen in 5 weeks. G. Just said that the solubility of nitrogen in *glycerol* is immeasurably small at 20°–25°. C. Müller, and A. von Hammel measured the solubility of nitrogen in glycerol and *chloral hydrate*. The latter gave at 15°:

Chloral hydrate	0	6·9	14·0	26·1	49·3	70·9	79·1 per cent.
β	0·01706	0·0164	0·0154	0·0141	0·0118	0·0131	0·0156
Glycerol	0	15·7	29·9	46·6	72·8	87·3	99·25 per cent
β	0·1707	0·01400	0·01087	0·00840	0·00552	0·00493	0·00524

C. Müller found for 11·38, 29·93, and 48·57 per cent. soln. of *sucrose*, at 15°, β=0·01480, 0·01053, and 0·00700 respectively; and G. von Hüfner gave at 20·16°–20·25°, the coeff. of absorption, β=0·01215, 0·01380, and 0·01480 for N, 0·5N-, and 0·25N-soln. of *dextrose;* 0·01221, for N-soln. of *lævulose;* 0·1203, *arabinose;* 0·01321, *erythritol;* 0·01213, *alanine;* 0·01212, glycerol; 0·01477, *urea;* and 0·01475, *acetamide.* J. Metschel discussed the supersaturation of soln. in ethyl alcohol, benzene, nitrobenzene, and aniline.

M. Berthelot[2] found quartz permeable to nitrogen at 1300°—*vide quartz* and glass. The adsorption of nitrogen by *platinum* has been studied by T. Graham, W. Hempel and G. Vater, and A. Sieverts; *iron, chromium, manganese, aluminium,* and *magnesium*, by A. P. Lidoff; *copper, silver*, iron, and *nickel*, by A. Sieverts and co-workers; silver, by F. Durau; *sodium*, copper, iron and nickel, by W. A. Dew and H. S. Taylor; *carbon*, by W. Hempel and G. Vater, F. Bergter, H. Briggs, G. Claude (at −182·5), G. Craig, J. Dewar, I. F. Homfray, J. Hunter, A. B. Lamb and co-workers, H. H. Lowry and S. O. Morgan, E. Reichardt, and A. Titoff. A. B. Berthollet observed that nitrogen adheres very tenaciously to *charcoal*—for the absorption by charcoal, *vide* carbon. J. B. Firth, R. E. Wilson, W. E. Garner, R. Chaplin, F. G. Keyes and M. J. Marshall, and S. McLean studied the adsorption of the gas by charcoal. A. G. R. Whitehouse gave 0·17–0·22 cal. per c.c., and

F. G. Keyes and M. J. Marshall, 3654 cals. per mol. for the heat of adsorption of nitrogen by charcoal. H. Rowe studied the adsorption at low press. The adsorption of nitrogen by *caoutchouc* was studied by T. Graham, A. d'Arsonval, H. A. Daynes, G. von Hüfner, and C. S. Venable and T. Fuwa ; *kieselguhr, pumice-stone, bone-ash,* and *iron-ore,* by W. Hempel and G. Vater ; *silica, stannic acid, alumina,* and *meerschaum,* by H. Briggs ; *mica,* by B. Iliin, and I. Langmuir ; *soils,* by H. E. Patten and F. E. Gallagher, and E. Reichardt ; *glass,* by I. Langmuir, F. Durau, F. H. Newman, and N. R. Campbell and co-workers ; *zinc oxide,* by H. N. Morse and H. B. Arbuckle, and T. W. Richards and E. F. Rogers ; *chabazite,* by R. Nacken and L. Wolff, and R. Seeliger ; *silica-gel,* by L. H. Reyerson and L. E. Swearingen ; and *iron hydroxides,* by F. Scheermesser. J. D. Edwards and S. F. Pickering found that if the permeability of rubber to hydrogen is unity, the value for nitrogen is 0·16.

§ 8. The Chemical Properties of Nitrogen

What of nitrogen? Is not its apparent great simplicity of action all a sham?—M. FARADAY.

Was kamm Wohl die Ursache sein, dass der Stickstoff, in seinen Vereinigungen seine Natur verandert?—J. J. BERZELIUS.

Nitrogen is the essentially romantic element, devil or god, according to circumstances.—*Lancet.*

Nitrogen at first sight appears to have but a small tendency to take part in chemical reactions. The negative behaviour of nitrogen is illustrated by the fact that it does not burn in air like hydrogen, and does not support combustion like oxygen. Its presence in a gas is assumed because of its inactivity; it does not respond to any of the usual tests. In fine, the most obtrusive characteristic of nitrogen is its chemical inertness, due, it is sometimes stated to " the great affinity of the atoms in the molecule for one another "; but, as G. Martin[1] has said, nitrogen possesses very powerful affinities for certain elements and very feeble affinities for others, just in the same way as oxygen or sulphur possesses very strong affinities for some elements and feeble ones for others, the only difference being that nitrogen exerts its greatest attraction on elements which are different from those upon which oxygen or chlorine exerts its greatest affinity. Nitrogen combined with other elements often exhibits great chemical activity. Nitrogen is the dominant element in the proteins—the essential constituent in our foods. It has been said that without proteins we die, this means that without nitrogen we die. It is a conspicuous element in hæmoglobin, and in the enzymes. There are other conspicuous nitrogen compounds like prussic acid, the alkaloids, artificial musk, indigo, and the azo-dyes. Nitrogen is the central figure in the chemistry of war, for it is an essential constituent of virtually all the useful explosives. In illustration, nitrogen chloride is possibly the most violent explosive known—but its energy is not sufficiently under control to allow it to be harnessed for use; potassium nitrate is the active agent in gunpowder; and the white and smokeless powders, and explosives are all nitrogenous—*e.g.* nitroglycerol, picric acid, trinitrotoluene, gun-cotton, etc. The power of nitrogen in explosives depends on the fact that when associated with oxygen it easily releases its partner, which is then taken up by the associated elements or compounds. The resulting oxidation occurs with explosive rapidity, and huge volumes of gas are formed instantaneously. At the same time, the nitrogen returns to what appears to be a more congenial state—gaseous nitrogen. In breathing, about 450 galls. of nitrogen pass through the lungs every 24 hrs., and this quantity would be sufficient to make 30 lbs. of nitrotoluene, or 40 lbs. of gun-cotton.

The idea that nitrogen is an inert gas with a disinclination to enter into chemical reactions is now said to be an ancient fiction; but it is still true that nitrogen is inert in the sense that it is difficult to initiate reactions in which free nitrogen takes part. It is usually necessary to raise the reacting components to a high temp. in order to inaugurate the reaction. This shows that nitrogen leaves its "state of chemical rest" with difficulty. The chemical inertness of nitrogen is sometimes attributed to the relative stability of the molecules. Once the molecule is under conditions where it must dissociate into atoms: $N_2 \rightleftharpoons 2N$, it becomes very reactive. Hence it requires a high temp. to make nitrogen unite with hydrogen, while iodine unites with hydrogen at a comparatively low temp. because its molecules are comparatively easily dissociated into atoms. In the absence of other data, G. Martin expressed the "affinity" of the elements for one another in terms of their relative heats of dissociation, and plotted, in three dimensions, the affinities of the elements with their group and series numbers in the periodic table, **1.** 6, 3. The relations of an element to the other elements can thus be represented by the distances from a horizontal plane, or by a kind of surface—the so-called *affinity surface.* That for nitrogen is represented by Fig. 7.

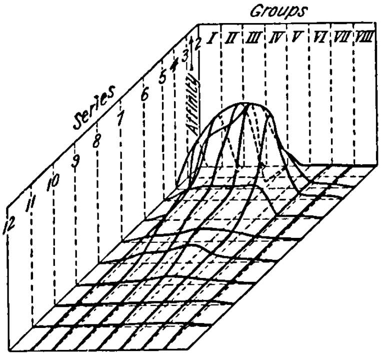

FIG. 7.—G. Martin's Affinity Surface for Nitrogen.

Nitrogen can under certain conditions be made to unite directly with **hydrogen** to form ammonia—*vide infra*—and quite a series of nitrogen hydrides is known. Active hydrogen was found by G. L. Wendt and R. S. Landauer,[2] Y. Venkataramaiah, and H. S. Hirst to act on nitrogen, forming ammonia—*vide infra,* the synthesis of ammonia—but H. S. Taylor, A. L. Marshall and H. S. Taylor, and E. Böhm and K. F. Bonhöffer failed to detect any action on nitrogen. E. J. B. Willey and E. K. Rideal said that nitrogen at 10 mm. press. forms ammonia when in contact with activated hydrogen. According to W. A. Noyes, gaseous hydrogen and nitrogen form ammonia in the presence of mercury vapour—possibly also some hydrazine is formed. The dissociation of the hydrogen caused by the resonance radiation of mercury is taken to be the important factor; and the number of molecules of ammonia formed is of the same order as the number of quanta in the incident radiation. J. N. Pring and E. O. Ransome found that when hydrogen is liberated electrolytically in contact with nitrogen at atm. press., 0·04 per cent. of ammonia was formed; at 60–104 atm., 0·09 per cent.; and at 300–500 atm., none was obtained. Hence the minute yield was due to thermal action, and not to the reaction between nitrogen and cathodic hydrogen—*vide infra,* the synthesis of ammonia. D. Berthelot and H. Gaudechon said that nitrogen and **oxygen** do not combine under the influence of light from a quartz mercury lamp—*vide supra,* the fixation of nitrogen. The direct union of nitrogen with oxygen to form the nitrogen oxides is discussed in connection with the so-called fixation of atm. nitrogen. N. Smith observed no signs of the formation of nitrite or nitrate when moist ferric oxide, stannic oxide, platinum, manganese dioxide, or lead dioxide is exposed to oxygen and nitrogen, nor was there any sign of oxidation of the nitrogen in the presence of tin, or of ferrous or manganous oxide; but some oxidation generally occurred in the presence of zinc, iron, magnesium, potassium, sodium, or cuprous oxide or chloride. W. T. David found that the combustion of hydrogen, carbon monoxide, or methane in air is favoured by ultra-red radiations; while W. T. David and co-workers showed that if the nitrogen of air be replaced by argon, oxygen, carbon dioxide, or the combustible gas itself, the ultra-red radiation has no effect. It is inferred that there is a temporary association between the molecules of nitrogen or of nitrogen oxides with those of the combustible gas tending to retard combustion, but this association is inhibited when the molecules of the combustible gas require vibrational energy by the absorption of ultra-red radiation with a resultant increase in the speed of combustion. Nitrogen is not oxidized by **ozone.** Further observations on the action of oxygen and ozone on nitrogen are discussed in connection with the fixation of nitrogen by oxidation. C. F. Schönbein, and T. S. Hunt supposed that ozone can oxidize nitrogen in the presence of alkalies, but L. Carius, and M. Berthelot were unable to confirm these observations. Both C. F. Schönbein, and M. Berthelot, however, showed that nitrous acid is formed along with ozone during the slow oxidation of phosphorus. Liquid nitrogen is a good solvent for liquids with a low b.p. Thus, H. Erdmann found that it readily dissolves liquid oxygen, and forms a clear blue soln. with liquid ozone. J. K. H. Inglis and J. E. Coates observed a small contraction when liquid oxygen and nitrogen are mixed, and A. Stock and C. Nielsen showed that with eq. proportions at —197°, the temp. rises about 0·5°, and the vol. contracts about 0·5 per cent. According to A. and P. Thénard, a mixture of **water** vapour and nitrogen, under the influence of an electric discharge, furnishes ammonium nitrite; M. Berthelot obtained a similar result with a strong induction current, but not with a feeble one. O. F. Tower observed that only traces of nitric oxide are formed when a mixture of nitrogen and water vap. is passed over an incandescent filament of rare earths at about 2000°. The attempt made by P. Villard to prepare *nitrogen hydrate* was not successful.

The affinity of nitrogen for the **halogens** is small; it is greatest for iodine and least for fluorine. H. Moissan[3] observed no sign of reaction between **fluorine** and nitrogen. O. Ruff and E. Giesel failed to make nitrogen fluoride. With **chlorine,** however, nitrogen forms a chloride (*q.v.*), and P. Hautefeuille and J. Chappius observed that if a mixture of chlorine, oxygen, and nitrogen is sparked, a white solid approximating $N_2Cl_2O_{13}$, or $Cl_2O_7.2NO_3$, is formed. Nitrogen possibly unites indirectly with **bromine** forming a questionable bromide (*q.v.*), and with **iodine** an **iodide** (*q.v.*). The affinity of nitrogen for the elements of the **sulphur** family is small. M. Berthelot[4] noted that nitrogen is oxidized when sulphur is burnt in compressed air in a calorimeter bomb. F. Richarz reported that when a sulphuric acid soln. of **persulphuric acid** is exposed to air, nitrous acid is formed, but M. Traube denied this, and stated that hydrogen dioxide, not nitrous acid, was responsible for the reactions on which F. Richarz based his conclusion. A. T. Larson and C. A. Black measured the solubility of nitrogen in liquid **ammonia** expressed in c.c. of gas at n.p.t. per gram of solvent:

	50 atm.			100 atm.			150 atm.		
	−25·2°	0°	19·0°	−25·0°	0°	22°	−22·0°	5·0°	13·3°
S	0·72	1·15	1·46	1·35	2·28	3·21	1·89	3·33	3·61

The affinity of nitrogen for the elements of the **phosphorus** family is feeble; nitrogen forms a phosphide. H. Moissan[5] found **tantalum** forms a nitride when heated to a high temp. in an atm. of nitrogen. The affinity of nitrogen for the elements of the **carbon** family is small. B. Iliin studied the adsorption of nitrogen by the carbon. O. Warburg and W. Brefeld discussed the activation of the iron in catalytic charcoal by nitrogen. M. Berthelot found that dried carbon does not unite with dry nitrogen under the influence of the electric discharge, but if water or hydrogen be present, **acetylene** is formed, and this with the nitrogen furnishes hydrogen cyanide. The reaction between acetylene and nitrogen was studied by W. E. Garner and co-workers. C. Lüdeking found that cyanogen is formed in the combustion of carbon in air. The synthesis of cyanides by the action of nitrogen on heated carbon, or on the carbon arc, was studied by J. E. Bucher, C. T. Thorssell, P. Askenasy and F. Grude, A. Frank and N. Caro, W. Moldenhauer and O. Dieffenbach, J. Moscicky, and A. König and W. Hubbuch. M. Berthelot found nitrogen is oxidized when carbon is burnt in compressed air in a calorimeter bomb; and he observed that under the influence of the silent discharge, nitrogen is absorbed by a number of organic products—**methane, benzene, terebenthine, cellulose, dextrin, thiophene, carbon disulphide,** etc. The influence of nitrogen on the speed of propagation of flame was examined by R. V. Wheeler and co-workers, H. B. Dixon, O. C. de C. Ellis and co-workers. H. Crouch and E. K. Carver studied the effect of nitrogen on the explosion limits of mixtures of methyl alcohol and of acetone with air. F. Garelle noted the tendency of nitrogen dissolved in benzene, bromoform, nitrobenzene, and cyclohexane to enter the solid phase and lower the f.p. about 0·005°. S. Miyamoto found that complex products were formed when mixtures of nitrogen with benzene or with ethylene are used. M. Berthelot, L. Hock, S. M. Losanitsch and M. Z. Jovitschitsch, S. M. Losanitsch, E. Briner and A. Baerfuss, E. Briner and E. L. Durand, H. P. Kaufmann, W. Loeb, L. Francesconi and A. Ciurlo, W. Dominik, A. König and W. Hubbuch, and E. Schüpbach studied the action of the silent discharge on mixtures of nitrogen and methane.

F. Wöhler and H. St. C. Deville showed that only at a white-heat does **silicon** react with nitrogen to form a nitride; H. Moissan observed a similar result with **titanium,** at about 800°; and J. W. Mallet, and E. Wedekind with **zirconium** at about 1000°. H. Moissan found that boron forms a nitride at a temp. above 1000°, but the affinity of nitrogen for aluminium and the other elements of that family is feeble. A. Rossel made a nitride of **aluminium,** and H. Moissan, and C. Matignon made nitrides of **thorium, cerium, lanthanum, praseodymium, neodymium,** and **samarium** by heating these elements in an atm. of nitrogen at a high temp. G. Ferée made **chromium** nitride in a similar way; H. Moissan, **tungsten** nitride, and **uranium** nitride, and A. Rossel, **iron** nitride. In the **magnesium** family, the affinity of nitrogen probably reaches a maximum with magnesium, and then falls to a low value towards zinc and thallium. H. St. C. Deville and H. Caron,[6] F. Brieglez and A. Geuther, and A. Rossel made magnesium nitride by heating the metal in an atm. of nitrogen. H. Erdmann found a burning magnesium wire is extinguished when plunged in liquid nitrogen. L. Maquenne, H. Moissan, A. Güntz, and A. Geuther made the nitrides of the alkaline earths—**barium, strontium,** and **calcium.** H. Erdmann said that a mixture of liquid nitrogen and calcium cannot be ignited in the ordinary way, but it can be ignited by a thermite cartridge. L. Ouvrard, and H. Deslandres made the nitride of **lithium** by direct union of the elements. The affinity of nitrogen for the alkaline earths and copper, silver, and gold steadily decreases from lithium to gold. R. Blondlot made **copper** nitride. G. Tammann observed that copper, and iron form much nitride when heated in nitrogen; cerium, lanthanum, **manganese,** chromium, **vanadium,** and titanium change colour; while silicon, **tantalum,** tungsten, **molybdenum, cobalt,** and **nickel** do not change colour.

§ 9. Allotropic Forms of Nitrogen

Near the beginning of the nineteenth century, there was some discussion as to whether nitrogen is an element or a compound. The controversy as to the possibility of nitrogen being a compound substance with water as the ponderable base recalls a similar dispute as to whether or not carbonic acid exists in chalk. Nitrogen was produced by passing water through a red-hot tube. G. Pearson,[1] and W. Henry obtained nitrogen by burning hydrogen and oxygen in hermetically sealed vessels; J. Priestley, by allowing oxygen to stand in contact with water; C. Girtanner, by boiling water in a glass vessel; and F. H. A. von Humboldt, by allowing earths to stand in a vessel containing atm. air whereby air is changed into nitrogen. Hence, said G. Girtanner, nitrogen is water deprived of its oxygen; or J. Mayer, nitrogen is composed of oxygen and hydrogen. J. C. Wiegleb, J. F. A. Göttling, F. Wurzer, and L. von Crell held similar views. It was shown by A. W. van Hauch, C. W. Jach, J. B. van Mons, N. T. de Saussure, C. L. Berthollet, and J. R. Dieman and co-workers, that "the nitrogen gas which, in some cases, is obtained by passing water-vapour through ignited tubes, proceeds merely from the external air, deprived of its oxygen by the fire in which the tubes are placed; and the supposed conversion of water into nitrogen, by combination with the matter of heat, is overthrown." Those who had synthesized nitrogen in other ways were also deceived by experiments in which the solubility of nitrogen in water, and the contamination of their gases, etc., with air was overlooked. This was not obvious because J. J. Berzelius, for instance, considered nitrogen to be a suboxide of an unknown element which he called *nitricum*. Ordinary nitrogen was supposed to be a compound of about 43 parts of nitricum and 57 parts of oxygen. The at. wt. of nitricum was given as 12·1–12·7. In 1809, H. Davy also stated: The decomposition and composition of nitrogen seem proved, and one of its elements appears to be oxygen; but what is the other elementary matter? Or is it that nitrogen is a compound of hydrogen with a larger proportion of oxygen than exists in water? In 1812, H. Davy agreed that nitrogen is an element. In 1820, J. J. Berzelius had given up nitricum, and, consonant with the ideas of A. L. Lavoisier, J. Dalton, and J. L. Gay Lussac, he recognized that the elementary nature of nitrogen is the only hypothesis in accord with the definition of an element. In 1862, T. S. Hunt called nitrogen, *le nitrile de l'acide azoteux*.

A. Morren,[2] E. Sarasin, E. Warburg, E. Goldstein, and E. P. Lewis noted that on passing a condensed induction discharge through rarefied nitrogen, a brilliant yellow luminescence is obtained, and that this luminescence persists for a considerable time after discontinuing the discharge. R. J. Strutt investigated the phenomenon, and showed that the gas in this condition can take part in many reactions which do not occur with ordinary nitrogen. An apparatus suitable for the purpose is illustrated diagrammatically in Fig. 8. A current of attenuated nitrogen is supposed to be passing along the tube *A* through which a jar discharge is passing. As the nitrogen passes into the vessel *B*, it appears as a "whirling cloud of brilliant yellow light." The luminous gas was found by A. Fowler and R. J. Strutt to give a characteristic spectrum showing green, yellow, and red bands of about equal intensity. According to R. J. Strutt, if the tube through which the gas is passing be heated at one point, the glow disappears, and if the tube be strongly heated, the glow is permanently extinguished. The intensity of the glow is increased by cooling in liquid air, but the glow is extinguished in the coldest part of the vessel. E. Tiede and E. Domcke stated that the after-glow of the active nitrogen that had been passed over heated copper is suppressed unless oxygen has been added to the nitrogen. The phosphorescence of sulphur, iodine, sodium, and other bodies which occurs when they are heated in nitrogen, through which has been passed an electric discharge, is attributed to the presence of oxygen, and not to the nitrogen having been rendered active. On the other hand, A. König and E. Elöd have shown that the phosphorescence will take place in nitrogen, free from every trace of oxygen, provided that metallic vapours, such as those of mercury, are also excluded. The glow is suppressed by the presence of a mere trace of mercury vapour, such as would be derived from the pump and manometer. On admitting a little oxygen, this mercury is oxidized, and the glow reappears, while the introduction of still more oxygen extinguishes it. H. B. Baker and R. J. Strutt also showed that the activation of nitrogen is not produced by traces of oxygen because nitrogen from which every trace of oxygen has been eliminated still showed the phenomenon, as did also the nitrogen prepared from potassium azide. Moreover, contrary to E. Tiede and E. Domcke, commercial nitrogen from a cylinder remained "active" after having been passed over copper heated to 400° to remove any residual oxygen. As a further proof that "active" nitrogen is a distinct modification of the element, there is the fact that it enters into combination with other substances. For example,

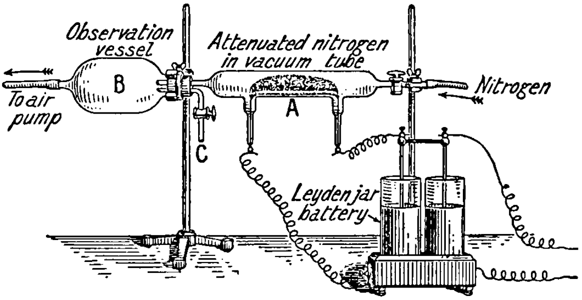

FIG. 8.—The Preparation of Active Nitrogen.

it acts upon different metals, such as mercury, to form nitrides ; while it decomposes certain organic compounds, with the formation of hydrogen cyanide. J. Kowalsky also confirmed these observations ; he observed the same phenomena with nitrogen from which special precautions were taken to eliminate every trace of oxygen. The orange glow of the " active nitrogen " was preceded by a series of minute explosions and an intense violet fluorescence. The explosions were attributed to the interaction of the active nitrogen and the mercury vapour, resulting in the formation of an explosive mercury nitride. The presence of mercury vapour (derived from the pump) in the gas was proved spectroscopically—the violet light showed the spectrum of mercury. Similar results were obtained by R. J. Strutt, M. Pirani and E. Lax, and F. Comte. A. G. Worthing and R. Rudy observed the excitation of the line spectrum of tungsten and nickel by activated nitrogen; and R. S. Mulliken, the excitation of the spectra of the copper halides. S. Karrer and co-workers examined the electrical conductivity of active nitrogen ; and N. H. Ricker, the luminosity. P. K. Kichlu said that the active nitrogen carries no free charge, and no charged particle of N_2. When sodium is acted on by activated nitrogen, the metal is ionized. A. G. Worthing studied the discharge of activated nitrogen; and C. Kenty and L. A. Turner, the surface layers of activated nitrogen on tungsten.

The nitrogen which has been exposed to the electric jar-discharge, is very active chemically, and is sometimes termed **activated nitrogen.** If the nitrogen be pure it does not become active under the influence of the jar-discharge—*vide supra*. The presence of a trace of foreign matter—oxygen, methane, ethylene, carbon oxides, hydrogen sulphide, or mercury vapour—is necessary for its production ; and N. R. Dahr also noted that the after-glow of nitrogen is increased by the presence of some of these gases. According to R. J. Strutt, the amount of oxygen necessary to produce the greatest effect gradually increases until it reaches a maximum of one part in 500, after which, the intensity of the glow decreases; and with 2 per cent. oxygen, the activity is destroyed. For the action of activated nitrogen on *oxygen*, and *ozone*, see the fixation of nitrogen by oxidation. Activated nitrogen gradually returns to normal nitrogen on standing, and very rapidly in the presence of oxidized copper. According to T. M. Lowry, air that has been subjected first to a silent and then to a sparking electric discharge shows the spectrum of nitrogen peroxide, apparently formed by the oxidation of a variety of nitrogen produced under the influence of the discharge. After a few seconds, this oxidizable kind of nitrogen reverts to a form which can no longer be oxidized either by oxygen or by ozone. R. J. Strutt's chemically active nitrogen is not oxidized by ozone under the conditions indicated above. The spectrum, etc., of the nitrogen after-glow was discussed by R. Rudy, E. P. Lewis, R. J. Strutt, R. T. Birge, A. E. Ruark and co-workers, K. T. Compton, A. S. Levesley, R. C. Johnson and H. G. Jenkins, and W. H. B. Cameron. It consists of the so-called α-, β-, and γ-groups—partly in the visible region and partly in the ultra-violet. The group supposed to originate from a metastable N_2 mol., lies in the red, yellow, and green ; the other groups, originating from a metastable NO molecule, are chiefly in the ultra-violet. R. C. Johnson and H. G. Jenkins did not find any other group in the ultra-violet. P. D. Foote and co-workers studied the energy of activated nitrogen; and E. J. B. Willey said that the heat of formation, -43 Cals. per mol., does not agree with the assumption that active nitrogen is atomic.

E. P. Lewis found that active nitrogen excites a strong green or bluish-green phosphorescence with uranium nitrate, uranium ammonium fluoride, zinc sulphide, barium chloride, strontium chloride, calcium chloride, and cæsium chloride, whereas a weak effect is given by lithium chloride, sodium chloride, potassium chloride, sodium iodide, potassium iodide, sodium carbonate, and strontium bromide. The phenomenon may be due to chemical reaction with the active nitrogen, or to the presence of free electrons. W. Jevons observed that the vap. of aluminium chloride produced a solid deposit which exhibited a bright green phosphorescence, but

H. Krepelka obtained no phosphorescence with aluminium bromide. E. Tiede and A. Schleede found that the phosphorescence is also shown by lithium fluoride, lithium carbonate, beryllium carbonate, beryllium oxide, barium platinicyanide, magnesium carbonate, calcium hexanitride, barium hexanitride, molybdic acid, terephthalic acid, and *iso*phthalic acid. It is noted that all these compounds contain nitrogen or an element of small atomic number. Sulphides and oxides of the second group of the periodic system show little or no effect. Ozone can also induce phosphorescence. The phenomenon is supposed by K. N. Bönhoffer and G. Kaminsky to be due to chemiluminescence, in which the decomposition of the activating substance furnishes the energy for luminescence. W. A. Bone and co-workers discussed the activation of nitrogen during the explosion of mixtures of air and carbon monoxide.

R. J. Strutt observed no chemical action between activated nitrogen and *oxygen*, or *hydrogen*. Activated nitrogen gives a bright blue flame with *iodine* vapour; and a pale blue flame with *sulphur*. When in contact with *sulphur chloride*, yellow nitrogen sulphide is formed; and with *carbon disulphide*, a blue polymerized nitrogen sulphide, and a polymerized carbon monosulphide are formed. Activated nitrogen reacts with *hydrocarbons* like *methane*, *pentane*, and *acetylene* to form hydrogen cyanide; when an acetylene flame is fed with a little activated nitrogen, the spectrum in each case shows the cyanogen bands. Solid and liquid products are formed along with the hydrogen cyanide: $C_2H_2+2N=2HCN$. Neither A. König and A. Elöd, nor E. J. B. Willey and E. K. Rideal observed any reaction with methane. R. J. Strutt observed a reaction with other organic vapours—*methyl bromide*, *ethyl iodide*, *chloroform*, *ethylene dichloride*, or *ethylidene dichloride*, *carbon tetrachloride;* and *benzene* appears to yield cyanobenzene—then cyanogen chloride is formed. Activated nitrogen reacts with *nitric oxide*, forming nitrogen peroxide in accord with the curious reaction: $2NO+N=NO_2+N_2$. The change is accompanied by a greenish-yellow flame resembling that produced when ozone reacts with nitric oxide. Activated nitrogen unites with ordinary *phosphorus*, some of which is simultaneously converted into the red form. It is not uncommon to find a mass of phosphorus behaving in a similar way when this element reacts with another substance. Activated nitrogen reacts with *arsenic* developing at the same time a faint green flame. The active nitrogen unites with the vapour of *mercury*, *sodium*, *cadmium*, or *zinc*, forming nitrides, which, when treated with alkali-lye or water, furnish ammonia. The product with mercury is explosive. White deposits containing combined nitrogen are formed when activated nitrogen reacts with *stannic chloride* or *titanic chloride*. In agreement with their hypothesis on the nature of active nitrogen—*vide infra*—E. J. B. Willey and E. K. Rideal found that chemical reaction with active nitrogen and other gases occurs only when the second gas has a critical increment below 55,000 to 60,000 cals. per mol. Thus no reaction occurs with hydrogen (heat of dissociation, 75,000–80,000 cals. per mol); oxygen; carbon monoxide; methene (80,000 cals. for the C—H-linkage); nitrous oxide (60,030 cals. per mol); and hydrogen chloride (90,000 cals. per mol). Reaction occurs with ammonia; nitric oxide (55,000 cals. per mol); hydrogen bromide (50,000 cals. per mol); hydrogen iodide (45,700 cals. per mol); the action with iodine (34,500 cals. per mol) is very marked; less so with bromine (46,200 cals. per mol); and still less so with chlorine (55,000 cals.).

R. J. Strutt suggested as a trial hypothesis that activated nitrogen is nitrogen in the atomic condition, although its chemical relationship to ordinary nitrogen resembles that between ordinary oxygen and ozone. Its production by the discharge: $N_2\rightleftharpoons 2N$ is a reversible reaction which attains a certain limit which is lowered if the conditions be less favourable. Thus, the gas should be at a low press., say a few mm. of mercury, since the collision of atomic with ordinary nitrogen mols. appears to destroy the activity; an uncondensed discharge, without the jar, or a steady high tension continuous current also destroys the activity. In support of this hypothesis there is also the anomalous behaviour of the after-glow in being sustained by heating, and destroyed by cooling—*vide supra;* and E. von Angerer's, and E. J. B. Willey and E. K. Rideal's observations that the reaction is bimolecular, for the rate at which the luminosity of active nitrogen disappears follows the bimolecular rule. The duration of the after-glow is about 30 seconds. At first, the glow is orange-yellow, and slowly changes to greenish-yellow. M. Duffieux favoured a second hypothesis, *viz.*, that the activation of nitrogen is produced by ionized atoms. He said that if the first positive group of nitrogen bands is ascribed to a diatomic mol. of mass 28, the second positive group (which predominates in the discharge on activation of nitrogen) and the negative group are due to the atom of mass 14 rather than to a metastable diatomic mol. In the conditions attending the emission of the two groups of bands, nitrogen atoms are present which are more likely to emit a band spectrum than none at all; the line spectrum attributed to the nitrogen atom is probably due to an ionized atom.

There is the third hypothesis that the activity is produced by unstable molecules. N. R. Dhar supposed that activated nitrogen is produced by the charging of the molecule to a certain potential by the electrical discharge, and that the activity is conditioned by the ease with which the molecules can give up their charge of energy. The luminescence is produced when the charge of energy is given up in the passage from the active to the inactive form. M. N. Saha and N. K. Sur inferred that active nitrogen consists of metastable N_2-mols. loaded with energy equivalent to 8·5 volts, because the spectrum of active nitrogen shows only those positive nitrogen bands attributed to non-ionized N_2-mol., and none of the line spectrum of nitrogen, or even the negative bands supposedly due to $N_2{}^+$. The excitation of the spectra of other materials by active nitrogen is due to the transference of the energy of the metastable state to the atoms of the other substances. In accordance with this view, no lines requiring more than 8·5 volts for their excitation are developed. Hydrogen and the inert gases have no influence on active nitrogen except a mere dilution of the glow. This is in accordance with the fact that the minimum excitation potential of these gases is much higher than the maximum energy which can be transferred by active nitrogen. This view is supported by R. J. Strutt's observation that nitrogen is activated to some extent by excited helium (19·2 volts). E. J. B. Willey and E. K. Rideal added that the argument is weakened by considering the effects of chemiluminescence since the heats of formation of the nitrides of magnesium, calcium, and barium are respectively of the order of 120,000, 112,000, and 199,000 cals. per mol. If the formation of magnesium nitride occurred through interaction between a metastable mol. of nitrogen with an energy of excitation of 2–3 volts and inactive magnesium, then the total energy liberated in combination, if expelled as monochromatic radiation, would be of the order of 8·5 volts. The passage of warm nitrogen over finely-divided magnesium does in fact produce chemiluminescence, a phenomenon more readily observed in the case of lithium. In addition, excited mercury atoms (4·9 volts) readily excite molecular hydrogen, whereas active nitrogen fails to do so. In support of the hypothesis that active nitrogen is nitrogen in a metastable, molecular form, R. J. Strutt found that the energy content of active nitrogen is approximately 1·2–1·8 times that of nitric oxide—namely, 26,000–39,000 cals. per mol., while I. Langmuir, and A. Eucken have shown that the heat of dissociation of nitrogen into atoms is greater than 190,000 cals. and probably of the order of 300,000 or 400,000 cals. per mol. The destruction of the after-glow by a second weak discharge observed by R. J. Strutt also suggests the deactivation of metastable mols. by electrons. A. Fowler and R. J. Strutt's observations (i) that no after-glow occurs when the discharge is such as to give only the line spectrum when nitrogen atoms are definitely present, and (ii) the absence of lines in the after-glow spectrum which would indicate the presence of atoms are not in agreement with the atomic hypothesis of activation, although M. Duffieux and others have shown that free atoms may give rise to band spectra. R. T. Birge favours the atomic hypothesis, but was formerly of the opinion that the α-bands of the after-glow spectra at least are due to metastable nitrogen mols.

at an energy level of 11·5 volts (9·3 volts electronic and 2·2 oscillatory), and that the β- and probably the γ-bands also are due to the presence of small traces of oxygen, perhaps in the form of excited nitric oxide—a view supported by the experiments of R. J. Strutt, and R. S. Mulliken. E. J. B. Willey and E. K. Rideal cited the above arguments, and showed that while the atomic hypothesis requires that the activation of nitrogen requires energy of the order of 300,000 cals. per mol activated nitrogen has a much smaller energy content, and they favour the hypothesis that active nitrogen consists of metastable molecules excited to a level of about 2·0 volts (43,800–41,000 cals.), a value comparable with the "oscillatory" energy of 2·2 volts (50,400 cals.) postulated by R. T. Birge. This relatively low energy content of active nitrogen is said to be consonant with the chemical reactivity of the gas, and may provide an explanation for the excitation of nitrogen in low voltage arcs observed by O. S. Duffendack and K. T. Compton. R. C. Johnson considers that the argument that activated nitrogen consists of metastable molecules with an energy about 42,500 cals. per mol, is not readily reconciled with spectroscopic data for the formation and decomposition of a quasi-stable molecule—*e.g.* N_2I_2, cannot account for the excitation of the 5061-iodine line, and activated nitric oxide molecules cannot account for the spectra which active nitrogen can excite. He therefore prefers the atomic hypothesis.

M. Trautz argued that the dominant constituent of activated nitrogen is triatomic nitrogen, **nitrozone**, or **triazone**, N_3, probably with an open chain structure, because nitrides, not azides, are formed—*vide infra*, mercuric nitride. On cooling, triatomic nitrogen reacts with monatomic nitrogen, forming ordinary nitrogen, N_2; and on heating, triatomic nitrogen forms monatomic and hexatomic nitrogen, N_6, which is present in the gas in very small quantities at low temp. The failure of all attempts to condense any form of active nitrogen led R. J. Strutt to conclude that the formation of triazone is not the cause of the activity. Ozone can be condensed from ozonized oxygen, but not nitrozone from activated nitrogen. However, J. J. Thomson's positive ray analysis (**4.** 25, 9) did reveal the presence of H_3-mols. when the gas is bombarded by anode rays. An active modification of nitrogen, possibly N_3, different from R. J. Strutt's form, was reported by F. L. Usher and R. Venkateswaran to be formed during the electrolysis of soln. of sodium azide, and a similar form, stated to attack mercury, was said by A. W. Browne and G. E. F. Lundell to be evolved at the anode during the electrolysis of soln. of potassium azide in hydrazoic acid at —78°. F. H. Newman found that the α-rays from polonium convert nitrogen into an active form thought to be a mixture of neutral atoms and triatomic mols. If the gas be in the presence of sodium, potassium, phosphorus, sulphur, iodine, magnesium, arsenic, mercury, or a sodium-potassium alloy, some gas is absorbed and in some cases nitrides are formed. G. L. Wendt considered that the failure of the test for nitrides with sulphur, phosphorus, and iodine is not evidence of the absence of chemical reaction. A. Eucken's allotropic α- and β-forms of nitrogen have been discussed in connection with the sp. ht. of nitrogen.

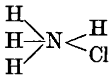
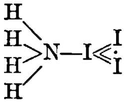
§ 10. The Valency of Nitrogen

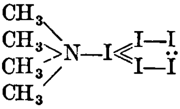
F. A. Kekulé[1] argued that nitrogen is tervalent because in the simplest hydride of nitrogen—ammonia, NH_3—the nitrogen atom behaves as if it were tervalent ; he believed that in ammonium chloride, NH_4Cl, the nitrogen atom is still tervalent if it be assumed that this salt is what he called a mol. compound. This hypothesis was supported by the vapour density observations of H. St. C. Deville and L. Troost, K. von Than, and L. von Pebal, in which the molecule was apparently dissociated : $NH_4Cl \rightarrow HCl + NH_3$. On the other hand, H. B. Baker, and F. M. G. Johnson found that, if thoroughly dried, ammonium chloride can be vaporized without dissociation occurring at all (**2**. 20, 16). This is in agreement with the quinquevalency of nitrogen. Graphically



The same argument, however, would make the nitrogen atom septavalent in R. Abegg and A. Hamburger's NH_4I_3, and nonavalent in C. Weltzien's $N(CH_3)_4I_5$.

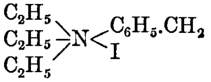
In these cases, however, it is assumed that the halogen may have a greater valency than unity, so that the nitrogen atom still remains quinquevalent:





This subject has been discussed by B. Rathke, A. Walter, F. W. Hinrichsen, J. C. Cain, etc.—*vide infra*, ammonium theory. V. Meyer and M. T. Lecco applied an ingenious experiment to test whether nitrogen be ter- or quinquevalent in the ammonium salts. It is agreed that it is tervalent in ammonia, NH_3. Then, like ammonia, (i) the alkyl amines combine directly with acids to form compounds resembling the ammonium salts, *e.g.* trimethylamine unites directly with hydrogen chloride to form trimethylammonium chloride: $N(CH_3)_3+HCl=NH(CH_3)_3Cl$; and (ii) the amines combine with methyl or ethyl iodides, etc., to form corresponding compounds. *E.g.* trimethylamine unites with ethyl iodide: $N(CH_3)_3+C_2H_5I=N(CH_3)_3C_2H_5I$. The properties of the compound $N(CH_3)_3C_2H_5I$ formed by the union of $N(CH_3)_3$ with C_2H_5I are identical with the compound $N(CH_3)_2C_2H_5.CH_3I$ formed by the union of $N(CH_3)_2C_2H_5$ with CH_3I. Consequently, it is inferred that the two compounds must have the same constitution; and that **the ammonium salts cannot be molecular compounds as postulated by F. A. Kekulé,** and that **the nitrogen in ammonium compounds is not tervalent but rather quinquevalent.** The argument is not quite sound, because, as W. Lossen showed, it is possible that the groups are rearranged during the formation of the compounds by the different processes, so that *the* most stable configuration is always formed; and one final product is obtained by the two different reactions. That the question is not definitely closed is illustrated by A. Werner's hypothesis for ammonium chloride H_3N . . . HCl, where the dotted line denotes an auxiliary valence with the nitrogen quadrivalent. There is nothing to show that one of the four hydrogen atoms of this salt is oriented differently from the other three. It will be observed that with quinquevalent nitrogen there is always at least one valency occupied by a group different from the others. According to W. Vaubel, and A. Lachmann, no compound is known with all five valencies occupied by similar radicles. When oxygen exerts its higher valencies, an analogous observation has been made with respect to it. Hence, it is assumed by L. Spicgel that after the three chief valencies of nitrogen are saturated, say with hydrogen, the remaining pair involve the separation of positive and negative charges, an hypothesis which can be formulated, $\ominus-NH_3-\oplus$.

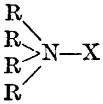
The three valencies of tervalent nitrogen are supposed to lie in one plane since attempts by V. Meyer, A. Ladenburg, E. Fischer, R. Behrend and E. König, F. Krafft, A. Reychler, F. S. Kipping and A. H. Salway, and H. O. Jones and J. P. Millington to prepare optically active derivatives have not been successful. On the other hand, J. A. le Bel, W. J. Pope and co-workers, M. B. Thomas and H. O. Jones, F. W. Fröhlich, E. Wedekind, and H. O. Jones have reported optically active derivatives of quinquevalent nitrogen—*e.g.* lævo- and dextro- α-benzoylphenylallylmethylammonium iodide; other examples are given by M. Scholtz. This is taken to mean that the fourth and fifth valencies of nitrogen are in a plane different from the other three. The experiment of V. Meyer and M. T. Lecco, cited above, is also taken to demonstrate the equivalency of the four valencies of quinquevalent nitrogen to which the alkyl groups are attached—subject, of course, to the limitation indicated by W. Lossen. Some of the alleged isomers are possibly simple cases of dimorphism. S. B. Schryvcr isolated two platinum salts of methyl-diethyl-isoamyl-ammonium chloride; and A. Ladenburg obtained two different triethylbenzylammonium iodides. The one salt is produced by the action of benzyl chloride on triethylamine followed by treatment with iodine; this compound readily parts with benzyl iodide when treated with hydriodic acid, and is supposed to be constituted $(C_2H_5)_3N{=}I(C_6H_5.CH_2)$. The other salt is formed by treating diethylbenzylamine with ethyl iodide; it does not yield benzyl iodide when treated with hydriodic acid; and it is supposed to be constituted:



$$\begin{matrix}C_2H_5\\C_2H_5\\C_2H_5\end{matrix}>N<\begin{matrix}C_6H_5.CH_2\\I\end{matrix}$$

A spatial or three-dimensional formula for nitrogen, analogous to the carbon tetrahedron, is not possible because there is no symmetrical solid figure with five corners. Hence it was assumed that certain valencies of the nitrogen atom are directed in special directions. Thus were obtained J. H. van't Hoff's cubic or tetrahedral formula, C. Willgerodt's double tetrahedron, C. A. Bischoff's square pyramid, and the modifications suggested by W. Vaubel, and A. von Baeyer. The tetrahedral and the pyramidal or square formulæ can be graphically symbolized:

$$\left[\begin{matrix}R\\R\end{matrix}>N<\begin{matrix}R\\R\end{matrix}\right]X$$



$$\begin{matrix}R\\R\\R\\R\end{matrix}>N-X$$

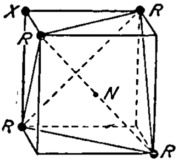


FIG. 9.—Tetrahedron Formula.

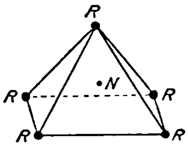

FIG. 10.—Pyramidal Formula.

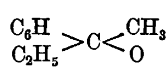
J. C. Cain's idea is that the group ≡N—Cl— acts at the centre of a tetrahedron like the group ≡C—. J. H. van't Hoff assumed that three of the five valencies are alike, while the other two are different because they are active only in special cases. He imagined the nitrogen as being inside a cube with its valencies directed towards five of these corners. By suitably selecting the position of the point representing the nitrogen atom, three of the valencies may be made equal in value, and the remaining two different from themselves and from the others. Analogous modes of representation were employed by A. Béhal, R. Behrend, G. J. Burch and J. E. Marsh, and C. Willgerodt. According to H. O. Jones, if one of the two valencies of the nitrogen atoms were predestined, so to speak, for an alkyl group, and the other for a negative radicle, then only one of the two optical isomers could be produced; but experience shows that the α- and β-forms are produced in equal proportions. Hence, it is assumed that while the three valencies of tervalent nitrogen may lie in one plane, the evocation of two more valencies produces a definite rearrangement whereby two compounds may be formed related to one another in form as object and its mirror image.

The X-radiogram of ammonium chloride by R. W. G. Wyckoff shows that the ammonium radicle persists as an independent entity in the crystalline state, for the crystals of that salt consist of aggregates of alternating ammonium and chloride radicles. H. O. Jones and J. G. M. Dunlop favoured the pyramidal formula; but W. H. Mills and E. H. Warren obtained salts of the type:

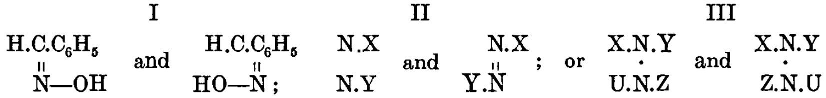
$$\left[\begin{matrix}H\\R_1\end{matrix}>C<\begin{matrix}CH_2.CH_2\\CH_2.CH_2\end{matrix}>N<\begin{matrix}CH_2.CH_2\\CH_2.CH_2\end{matrix}>C<\begin{matrix}H\\R_2\end{matrix}\right]X$$

which are capable of being resolved into optical isomerides. This is taken to be in harmony with the tetrahedral but not with the pyramidal hypothesis. The stereochemistry of the four radicles of the ammonium ion were thought by A. Werner to be identical with those of methane; and the optically active methylethyl aniline oxide of J. Meisenheimer can be represented as a quadri-covalent compound without embarrassment with respect to the semi-polar double-bonded oxygen:



$$\begin{array}{c}C_6H\\C_2H_5\end{array}\!>C<\!\begin{array}{c}CH_3\\O\end{array}$$

A. Hantzsch and A. Werner[2] assumed that in certain compounds the third valency of the tervalent nitrogen atoms does not necessarily lie in the same plane as the other two. This hypothesis, that the three bonds of a doubly-bound atom of nitrogen in the oximes and related compounds are not co-planar, was strengthened by the work of W. H. Mills and A. M. Bain, and W. H. Mills and H. Schindler. T. M. Lowry said that whatever opinion is held as to the asymmetry of the trisubstituted ammonia from which it is derived, the nitrogen atom of the pyrrolidine ring of the nicotinium ion must be regarded as asymmetric, a deduction which receives support from the fact that nicotine acetate has $[\alpha]_D=+18{\cdot}85°$, whilst nicotine has $[\alpha]_D=-169°$. The anomaly is not observed in cases where the formation of a salt is unaccompanied by fundamental change in the character of the asymmetric system. A. E. Uspensky discussed the spatial distribution of the valency directions of tervalent nitrogen. In certain compounds, the three valencies of the nitrogen atom act towards the corners of a, not necessarily regular, tetrahedron, in whose fourth corner, the nitrogen atom is itself situated. This may give three cases of isomerism:



$$\begin{array}{cccccccccc} & \text{I} & & & \text{II} & & & & \text{III} & \\ H.C.C_6H_5 & & H.C.C_6H_5 & N.X & & N.X & & X.N.Y & & X.N.Y\\ \| & \text{and} & \| & & \text{and} & \| & ;\ \text{or} & \cdot & \text{and} & \cdot \\ N{-}OH & & HO{-}N; & N.Y & & Y.N & & U.N.Z & & Z.N.U\end{array}$$

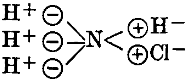
The hypothesis was discussed by K. Auwers and V. Meyer, H. Goldschmidt, E. Müller, A. Hantzsch, E. Beckmann, etc. In order to distinguish between these isomeric forms of, say, the benzaldoximes, A. Hantzsch employs the term **syn** as a prefix to indicate that the hydroxyl group lies on the same side of the mol. as the hydrogen atom of the aldehyde, and **anti** when the hydrogen and hydroxyl lie on opposite sides of the mol. The same nomenclature is applied to other compounds, *e.g.* the potassium benzoylphenyldiazotates, etc. Thus:

$$\begin{array}{ccccccc} C_6H_5.C.H & & C_6H_5.C.H & & R{-}N & & R{-}N\\ \| & \text{and} & \| & ; & \| & \text{and} & \| \\ N{-}OH & & HO{-}N & & KO{-}N & & N{-}OK\end{array}$$

Syn-aldoxime. *Anti*-aldoxime. *Syn*-diazotate. *Anti*-diazotate.

This subject is discussed in special memoirs: E. Wedekind, *Die Entwicklung der Stereochemie des funfwertigen Stickstoffs im letzten Jahrzehnt*, Stuttgart, 1909; *Stereochemie*, Leipzig, 1904; J. H. van't Hoff, *The Arrangement of Atoms in Space*, London, 1898; *La chimie dans l'espace*, Rotterdam, 1875; Oxford, 1891; A. W. Stewart, *Stereochemistry*, London, 1919; J. N. Friend, *The Theory of Valency*, London, 1915; H. Kaufmann, *Die Valenzlehre*, Stuttgart, 1911; A. Eiloart, *A Guide to Stereochemistry*, New York, 1893; C. A. Bischoff and P. Walden, *Handbuch der Stereochemie*, Frankfurt, 1894; C. A. Bischoff, *Materialen der Stereochemie*, Braunschweig, 1904; L. Mamlock, *Stereochemie*, Leipzig, 1907; P. Freundler, *La Stéréochimie*, Paris, 1899; P. Bruylants, *La valence chimique*, Louvain, 1912; K. Auwers, *Die Entwicklung der Stereochemie*, Heidelberg, 1890; W. Meyerhoffer, *Stereochemie*, Leipzig, 1892; E. G. Mond, *Stéréochimie*, Paris, 1895; A. Hantzsch, *Grundriss der Stereochemie*, Breslau, 1893; W. van Ryn, *Die Stereochemie der Stickstoffs*, Zürich, 1897; W. Vaubel, *Stereochemische Forschungen*, München, 1899.

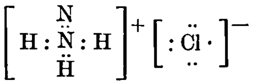
According to R. Abegg's theory[3] of co-valency (**4.** 27, 3), nitrogen has three negative and five positive valencies. The positive valencies are illustrated by the oxides and halides; whereas in ammonia, the three negative valencies of nitrogen are saturated. In ammonium chloride, the positive and negative valencies are represented by the scheme:



$$\begin{array}{l}H^+\ominus\\H^+\ominus\\H^+\ominus\end{array}\!>N<\!\begin{array}{l}\oplus H^-\\\oplus Cl^-\end{array}$$

The attachment of the fourth hydrogen atom by a weak positive or contra-valency is supposed to explain the ready dissociation of that salt on heating. J. N. Friend, and F. Wenzel have described a modification of this hypothesis. F. Wenzel attempted to account for the behaviour of nitrogen compounds on the assumption that the valencies of nitrogen are divisible into two distinct groups, one of which includes two and the other three valencies which are equal in all respects. When quinquevalent nitrogen is transformed into tervalent nitrogen there is a loss of one valency from each group. This change is supposed to result in the formation of an intra-atomic double linking connecting dissimilar nuclei. In support of this theory attention is directed to the similarity between the amines and ethylene derivatives in respect of their capacity to form additive compounds. F. Wenzel said that there is no satisfactory evidence to support the view that four of the nitrogen valencies bear the same relation to the fifth. Whilst certain chemical observations suggest that there are two pairs of valencies which are identical in relation to the fifth valency, physico-chemical data indicate that there are three valencies which are identical with regard to the fifth valency. From this it is inferred that the fifth valency does not always represent one and the same valency unit. R. De, and J. Picard and J. H. Dardel discussed the valency of nitrogen from the point of view of the co-ordination theory. The electronic structure of ammonia, and ammonium chloride can be represented:

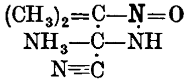
$$\begin{array}{c}\mathrm{H}\\ \mathrm{H}:\underset{\cdot\cdot}{\ddot{\mathrm{N}}}:\mathrm{H}\end{array}$$



$$\left[\begin{array}{c}\mathrm{N}\\ \mathrm{H}:\ddot{\mathrm{N}}:\mathrm{H}\\ \ddot{\mathrm{H}}\end{array}\right]^{+}\left[:\underset{\cdot\cdot}{\ddot{\mathrm{Cl}}}\cdot\right]^{-}$$

and this fits in with the hypothesis of A. Werner and with that of J. H. van't Hoff —*vide supra*—namely, that *the four positive radicles of the ammonium salts are tetrahedrally disposed.* A. A. Blanchard added that nitrogen can have but eight and hydrogen but two electrons in its valency shell although phosphorus may have more than eight. Defining the non-polar valency as the number of pairs held in common with other atoms, nitrogen can have a maximum non-polar valency of four. The polar valency may be regarded as plus five if we define it as the net charge of the nitrogen kernel, or as minus three if we define it as the charge of the nitrogen atom and consider the eight electrons of the shell as a part of the atom. The subject was discussed by J. H. W. Booth, and E. Müller.

In nitric oxide, the nitrogen atom behaves as if it were *bivalent* or *quadrivalent.* The latter is assumed because the mols. of nitric oxide, NO, do not associate at temp. as low as —100°. If association did occur, it would be attributed to the activity of either the oxygen, $N{=}O{=}O{=}N$, or the nitrogen, $O{=}N{=}N{=}O$. The unsaturated nature of the nitric oxide mol. is shown by its immediate formation of nitrogen peroxide, N_2O_4, in the presence of free oxygen. The rupture of the oxygen mol. during this reaction is shown by the fact that when heated, the nitrogen peroxide does not dissociate into nitric oxide and oxygen, but into single mols.: $N_2O_4 \rightleftharpoons 2NO_2$. F. Raschig's[4] idea that potassium peroxylaminesulphonic acid, $(KO.SO_2)_2{=}N{=}O$, contains quadrivalent nitrogen was questioned by T. Haga, who doubled the formula so as to furnish $(KO.SO_2)_2{=}N{-}O{-}O{-}N{=}(KO.SO_2)_2$. O. Piloty and B. Schwerin stated that the porphyrexine which they prepared contained quadrivalent nitrogen, say:



$$\begin{array}{rcl}(\mathrm{CH_3})_2{=}&\underset{\cdot}{\mathrm{C}}&{-}\underset{\cdot}{\mathbf{N}}{=}\mathrm{O}\\ \mathrm{NH_3}{-}&\underset{\cdot}{\mathrm{C}}&{-}\mathrm{NH}\\ \mathrm{N}{\equiv}&\mathrm{C}&\end{array}$$

but the hypothesis has not been confirmed. F. H. Banfield and J. Kenyon prepared oxidation products of a substituted hydroxylamine which they supposed to contain quadrivalent nitrogen: $R_2{=}N{-}OH \rightarrow R_2{=}N{=}O$; but T. M. Lowry showed that the reaction can be explained by assuming the nitrogen tervalent throughout. C. W. Blomstrand, F. Barker, and A. P. Mathews also put forward the hypothesis that nitrogen can act as a *univalent* element. There is no satisfactory evidence to support this assumption.

§ 11. The Atomic Weight of Nitrogen

According to H. E. Roscoe and A. Harden,[1] J. Dalton first deduced the value 4 for the eq. weight of nitrogen from an old analysis of ammonia by W. Austin, and later from the analysis of ammonia by C. L. Berthollet, and of nitrogen oxide by H. Davy ; he gave 5 for the at. wt. of nitrogen. In 1811, J. J. Berzelius analyzed ammonium chloride and obtained 14·22–14·66 for the at. wt. of nitrogen. In 1820,

J. J. Berzelius and P. L. Dulong showed that the vap. density of nitrogen gas is in agreement with the views of L. Gmelin, W. Prout, and J. J. G. Meinecke, who gave 14 for the at. wt. of nitrogen. L. Gmelin obtained 14·08 from the ratio Ag : $AgNO_3$; F. Penny, 13·98–13·99; J. C. G. de Marignac, 13·99–14·005; J. S. Stas, 14·00–14·049; W. L. Hardin, 14·015–14·037; and T. W. Richards and G. S. Forbes, 14·008–14·031 with Ag=107·880–107·92. J. C. G. de Marignac obtained 13·98 from the ratio Ag : NH_4Cl; J. Pelouze, 13·96; J. S. Stas, 14·014–14·027; and A. Scott, 14·007–14·111. J. S. Stas obtained 14·042–14·045 from the ratio Ag : NH_4Br; and A. Scott, 14·005–14·011. E. Turner obtained 14·01–14·03 from the ratio $AgNO_3$: AgCl, and F. Penny, 14·01–14·025. A. Scott obtained 14·014–14·017 from the ratio NH_4Cl : AgCl. J. C. G. de Marignac calculated 14·07–14·08 from the ratio KCl : $AgNO_3$; and J. S. Stas, 14·05–14·06; J. S. Stas obtained 14·003–14·006 from the ratio $AgNO_3$: NH_4Cl. G. Dean calculated 14·02–14·03 from the ratio KBr : AgCy. L. F. Svanberg calculated 13·91 from the ratio $Pb(NO_3)_2$: PbO. F. Penny obtained 14·05 from the ratio KCl : KNO_3; J. S. Stas, 14·04–14·05; and J. G. Hibbs, 14·03–14·04. F. Penny obtained 14·02–14·03 from the ratio NaCl : $NaNO_3$; J. S. Stas, 14·04–14·05; and J. G. Hibbs, 14·010–14·022. F. Penny obtained 14·02 from the ratio $KClO_3$: KNO_3, and 14·05 from the ratio $NaClO_3$: $NaNO_3$. J. Thomsen obtained 14·024–14·028 from the ratio NH_3 : HCl; and T. W. Richards and E. H. Archibald, 13·992–14·005 from the ratio $2KNO_3$: K_2O, and 14·004–14·018 from the ratio $2CsNO_3$: Cs_2O. From the gas analyses of P. A. Guye and co-workers, they calculated 14·007 from the ratio N_2O : O, and 14·010 from the ratio N_2 : O; A. Jaquerod and S. Bogdan, 14·015 from the ratio N_2O : N_2; and R. W. Gray, 14·009–14·011 from the ratio NO : N, and 14·009 from the ratio N : O.

From the density determinations of A. Leduc, D. Berthelot, P. A. Guye and L. Friderich, Lord Rayleigh, A. Jaquerod and F. L. Perrot, and R. W. Gray, the value 14·009 is derived from the ratio N_2 : O_2 for the at. wt. of nitrogen; D. Berthelot, Lord Rayleigh, A. Leduc, and P. A. Guye, 14·006 from the ratio N_2 : CO; A. Leduc, Lord Rayleigh, and P. A. Guye and A. Pintza, 14·007 from the ratio N_2O : CO_2; P. A. Guye, and P. A. Guye and A. Pintza, Lord Rayleigh, and A. Leduc, 14·006 from the ratio N_2O : O_2; A. Jaquerod and O. Scheuer, P. A. Guye, and R. W. Gray, 14·008 from the ratio NO : O_2; P. A. Guye and A. Pintza, and E. P. Perman and J. H. Davies, 14·010 from the ratio NH_3 : O_2; H. V. Regnault obtained 14·056, H unity; and M. Vezes, 14·040, oxygen 16. By the method of limiting densities, D. Berthelot obtained 14·007 from N_2, 13·997 from N_2O, hydrogen 1·0077. A. Leduc obtained 14·008 by the method of corresponding vol.; T. Bateiecas, 14·005; G. P. Baxter and H. W. Starkweather, 14·007; and G. M. Maverick, 13·996 from compressibility data; and P. A. Guye, 14·007, by the method of critical constants. By considering all the data, F. W. Clarke derived 14·0101, oxygen 16; G. D. Hinrichs, 14 ± 0·001, oxygen 16; B. Brauner, 14·010; J. D. van der Plaats, 14·0421; W. Ostwald, 14·0410; and E. Moles and J. M. Clavera, 14·008. The International Table of Atomic Weights (1924) gave 14·01 for the at. wt. of nitrogen—oxygen 16.

The **atomic number** of nitrogen is 7. F. W. Aston[2] found no **isotopes,** there being only one form of atom of mass 14; J. L. Costa obtained a value greater than 14 and less than 14·008; E. Rutherford and J. Chadwick reported that they had succeeded in the **disintegration of the nitrogen atom.** They bombarded nitrogen gas with α-particles derived from radium-C, and obtained long-range particles of hydrogen nuclei which are assumed to have been knocked away from the nitrogen atoms during the collision. About one impact of the α-particles with the nitrogen atom out of twelve succeeds in breaking up the atom. The subject was discussed by E. Chalfin, G. Kirsch and H. Pettersson, R. W. Millar, G. Kirsch, W. Lenz, V. Kondratjeff, H. T. Wolff, P. S. M. Blackett, W. D. Harkins and H. A. Shadduck, and A. Smekal. For the transmutation of nitrogen into helium, hydrogen, and neon, by R. W. Riding and E. C. C. Baly, *vide* **7.** 48, 6. A. L. Foley studied the effect on the spectra of the exposure of nitrogen, confined in sealed glass tubes, to ultra-violet light, and to the X-rays, but with no definite results.

According to N. Bohr, the **electronic structure** of the atom of nitrogen is as follows: There are two electrons in the first ring about the central nucleus or proton, four in the second, and one in the third or outer ring: (2) (4, 1). From the general similarity in the physical properties of carbon monoxide and nitrogen, I. Langmuir inferred that there is a resemblance in the electronic structure of the two mols. (**4**. 27, 4). P. D. Foote suggested that the presence of occluded nitrogen in uraninite shows that the atom of uranium possibly contains nitrogen nuclei. H. G. Grimm and A. Sommerfeld, F. P. Worley, W. A. Wahl, H. Nagaoka, I. S. Bowen and R. A. Millikan, J. C. McLennan and co-workers, P. M. S. Blackett, R. A. Birge, J. H. Jones, I. Woodward, J. R. Partington, A. O. Rankine, K. R. Ramanathan, G. Kirsch, H. Collins, H. Burgarth, A. W. C. Menzies, H. Lessheim and R. Samuel, E. C. Stoner, G. P. Thomson and R. G. J. Frazer, C. D. Niven, M. L. Huggins, etc., studied the electronic structure.

§ 12. The Nitrides

The metals lithium, magnesium, boron, and aluminium form a mixture of oxides and nitrides when oxidized in air; and the elements lithium, calcium, strontium, barium, magnesium, boron, aluminium, the rare earth metals, silicon, titanium, zirconium, cerium, thorium, vanadium, columbium, tantalum, chromium, uranium, and manganese form **nitrides** when heated in an atm. of nitrogen. Instead of the metal, the amalgam can be used as with Ca, Ba, and Mn; a mixture of the metal oxide and carbon—B, Al, Si, and Mg; a mixture of the metal oxide and carbon—Bi, Si, Ti, Mg, and V; a mixture of the metal oxide and magnesium or aluminium—Ce, La, Nd, Pr, and U; the metal carbide—Ba, Sr, and Ca (cyanides may be formed); or the metal hydride—Bi, Si, Ti, Ca, Ba, Sr, Mg, and V. Nitrides have also been made by the action of activated nitrogen on the metal. The nitrides can also be produced by heating many metals in ammonia—K, Cu, Ba, Mg, Zn, Cd, B, Al, Ti, Th, Cr, Mo, Mn, Fe, Co, and Ni. Instead of the metal, the amalgam can be used—Fe and Mn; the metal oxide—Cu, Hg, B, Ti, and Cb; the metal carbide—Th; the metal chloride—Si, Ti, Zr, Th, Cr, Mo, W, U, Cb, Ta, V, and Fe; the metal bromide or iodide—Bi, and Fe; and the metal nitrate—Cu (and liquid ammonia). The nitrides are also produced by heating the metal and calcium carbide in air—Zn, Al, and Fe; the metal and aluminium in air—Zr; the metal and lime in air—Al; the metal and soda or carbon in air—Al; the metal oxide and carbon in air—Ti, and B; the metal oxide and magnesium in air—Ca, Sr, Ba, Al, and Zr; the metal and nitrogen trioxide—Bi. The nitrides may also be formed by the decomposition of an amide or imide—K, Ba, Cu, Cd, Zn, and B; by the action of cyanides or by heating the metal in cyanogen;[1] and by double decomposition with other nitrides—*e.g.* copper oxide and magnesium nitride give copper nitride.

In the normal nitrides, nitrogen is tervalent so that the general formula of the nitrides of the univalent elements is R_3N; of the bivalent elements, R_3N_2; of the tervalent elements, RN; of the quadrivalent elements, R_3N_4; and of the quinquevalent elements, R_3N_5. The compounds of the metals with the univalent radicle, N_3, are salts of hydrazoic acid, HN_3, and are called azides—*vide infra.* The relationship of the nitrides to ammonia is shown by the evolution of ammonia when the soluble nitrides are treated with water, an acid, or alkali-lye; or when the insoluble nitrides are fused with alkali hydroxide. Usually the nitride is decomposed by steam giving off ammonia; but in the case of cerium nitride, some hydrogen is simultaneously formed. When the nitrides are oxidized, free nitrogen is evolved and an oxide of the metal is formed. Only in the case of boron nitride is some nitrogen simultaneously oxidized.

Among the alkali metals, lithium is exceptional in readily combining directly with nitrogen, but sodium, potassium, rubidium, and cæsium do not form nitrides when heated in nitrogen under ordinary conditions. H. Deslandres[2] found that the combination with lithium occurs even at ordinary temp. L. Ouvrard prepared **lithium nitride**, Li_3N, by heating gradually to dull redness lithium contained in an iron boat in a current of nitrogen. The metal becomes incandescent and the nitride is formed. A. Guntz found the product so obtained was contaminated with 2–8 per cent. of iron, but the result was no better if a vessel of nickel, quartz, or carbon be employed; silver, and platinum are dissolved by molten lithium. F. W. Dafert and R. Miklauz said that the lithium unites with pure dry nitrogen even at ordinary temp., forming the nitride; the presence of relatively small proportions of oxygen or hydrogen completely prevents the reaction so that lithium is not attacked by dry air at room-temp. W. Frankenburger measured the velocity of formation of lithium nitride from the metal and nitrogen between —55° and —30°, and found it to be proportional to the surface of the formed nitride $-dp/dt=KM^{\frac{2}{3}}$. He also found that $k=CT^{\frac{1}{2}}e-Q/RT$; and that the increase in the velocity with temp. depends on the increase in the fraction, $e-Q/RT$, of the total number of collisions which take place between the lithium surface and the N_2-molecules. This gives the number of collisions possessing an energy $Q=16{\cdot}4$ cals. per mol. At 240° K., this fraction is approximately $1{\cdot}2\times10^{-15}$. The value for C between —55° and —30° is $C=2{\cdot}153\times10^{31}$. The term $CT^{\frac{1}{2}}$ is equal to the number of collisions, S per sec. at $T°$, on the surface of the lithium. The number of collisions for a gas of mol. vol. v is known to be $(N/v)(RT/2\pi M)^{-\frac{1}{2}}$ per sq. cm. per sec.; and with a surface 50 sq. cm. $ST^{-\frac{1}{2}}=1{\cdot}01\times10^{24}$. This, taken in conjunction with C, shows that the velocity of the reaction is greater by the fraction 21×10^6 than would be the case if only the collisions with a heat of activation of 16·4 cals. were chemically fruitful. C. Urfer prepared lithium nitride by heating an amalgam to about 600° in an atm. of nitrogen. Lithium nitride furnishes a spongy black mass which is readily attacked by water, forming ammonia and lithium hydroxide. W. Frankenburger found that the X-radiogram shows that the crystals of lithium nitride belong to the cubic system; that the space-lattice has a side of 5·5 A., and that each cell has 4 atoms of nitrogen, and 12 atoms of lithium. R. Brill also examined the space lattice of lithium nitride, and found it to be analogous to that of ammonia, NH_3. F. W. Dafert and R. Miklauz found that lithium nitride melts at 840°–845°. A. Guntz gave for the heat of soln., 131·1 Cals.; and for the heat of formation: $3Li_{solid}+N_{gas}=Li_3N_{solid}+49{\cdot}5$ Cals.; A. Guntz and F. Benoit gave 33 Cals. Lithium nitride gives the hydride when heated in a current of hydrogen: *e.g.* $Li_3N+3H_2=NH_3+3LiH$. According to A. Guntz, lithium nitride reacts with a large number of the metal chlorides, MCl, forming the metal nitride: $Li_3N+3MCl=M_3N+3LiCl$. The thermal value of the reaction is usually high because lithium chloride is formed with rather a large evolution of heat. F. W. Dafert and R. Miklauz said that the fused nitride rapidly attacks iron, nickel, copper, platinum, porcelain, and other silicates. At 870°, it will eat through any known containing vessel. It penetrates through magnesia vessels as through a filter. For the products formed by the action of hydrogen, *vide infra*, lithium amide and imide. A. Remelé observed the photoelectric effect with lithium nitride. L. Zehnder said that **sodium nitride**, Na_3N, is formed when metallic sodium is made the cathode for an electric discharge in nitrogen gas. The black product collects on the walls of the tube in the vicinity of the anode. When heated, the nitride is said to decompose into nitrogen and sodium; and to be decomposed by water with the evolution of nitrogen, but G. Salet showed that the gas given off is ammonia. H. Hardtung was unsuccessful in an attempt to make the nitride by heating sodium at 250°–400° in dry nitrogen. J. L. Gay Lussac and L. J. Thénard reported that a black nitride is formed when sodamide is heated, but A. W. Titherley was unable to confirm this. F. Fischer and F. Schröter prepared sodium nitride mixed with free sodium, in the apparatus illustrated diagrammatically in Fig. 11. A glass tube, *A*, contains a platinum cathode, *B*, fused into the glass. The movable anode, *C*, is made of the metal whose nitride is desired. The gap between anode and cathode is regulated by rotating the stopper *D* which is fitted with a screw-thread as shown. The stopper is sealed by the mercury in the cup *S*. The side-tubes *F* and *G* are used for collecting the nitride formed in the lower part of the tube. Liquid nitrogen is placed in the lower part of *A*, an arc is established, and the vap. of the required element and nitrogen is raised locally to a high temp., and then quickly cooled by the excess of liquid surrounding the arc. A mixture of nitrogen with nine times its vol. of argon was employed; this increases the rate of disintegration of the metal electrode. The resulting black sodium nitride when heated gives off nitrogen with explosive violence; and it dissolves in water with the evolution of ammonia. J. L. Gay Lussac and L. J. Thénard reported **potassium nitride,** K_3N, to be formed, as a greenish-black, infusible mass, by heating potassium amide to redness in a closed vessel. A. W. Titherley was unable to verify this with the amide he prepared; but H. Davy confirmed J. L. Gay Lussac and L. J. Thénard's observation, and added that a black product is formed at a higher temp. It is decomposed at a high temp. into its elements; it generally takes fire spontaneously in air, burning with a dark red flame. It gives off nitrogen when burnt in oxygen, or when heated with mercuric oxide. It effervesces violently with water with the evolution of ammonia: $K_3N+3H_2O=3KOH+NH_3$. It unites with phosphorus or sulphur when heated, forming a highly inflammable mixture, which, coming in contact with water, evolves ammonia and phosphine or hydrogen sulphide. F. Fischer and F. Schröter obtained it as a blue compound by the method illustrated in Fig. 11. The product resembled sodium nitride in its chemical properties. H. Moissan prepared **rubidium nitride,** Rb_3N, by heating rubidium hydride in a current of nitrogen—some rubidium amide is formed at the same time. F. Fischer and F. Schröter prepared rubidium nitride as a blue compound by the method depicted in Fig. 11. H. Moissan reported **cæsium nitride,** Cs_3N, to be formed by the method he employed for rubidium nitride. The alkali nitrides burn in air, and they are readily attacked by chlorine, phosphorus, and sulphur; water decomposes them quantitatively into the metal hydroxide and ammonia; and dil. acids give ammonia and the corresponding salt. R. Suhrmann and K. Clusius observed that the m.p. of potassium nitride is 343° and its decomposition temp. 355°; rubidium nitride melts at 321° and decomposes at 395°; cæsium nitride melts at 326° and decomposes at 390°; while sodium nitride decomposes at 275° below its m.p.

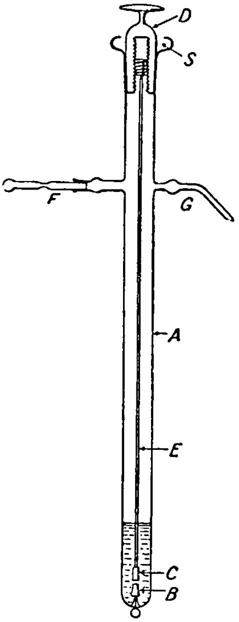

FIG. 11.—Apparatus for making Nitrides.

P. L. Aslanoglou[3] found that powdered copper heated in an atmosphere of nitrogen does not form a nitride; and K. Iwase, and I. I. Shukoff observed no absorption of nitrogen by the metal at 1250°. G. Tammann, however, said that a nitride is formed. K. Iwase found nitrogen is absorbed by liquid copper. The observations of L. J. Thénard, F. Savart, C. Despretz, R. Blondlot, H. N. Warren, C. Matignon and R. Trannoy, C. H. Pfaff, C. W. J. Kastner, W. R. Grove, J. F. Daniell, H. Pauli, A. Rossel, and L. Arons on this subject have been discussed in connection with the action of nitrogen and of ammonia on copper (**1**. 21, 6). According to A. Schrötter, and H. Herzer, **cuprous nitride,** Cu_3N, is produced by the action of ammonia on cupric oxide at, say, 250°, for 120 hrs.: $6CuO+4NH_3=2Cu_3N+6H_2O+N_2$. The rate of formation is therefore very slow. If the temp. is too high, the metal alone is produced. The product is contaminated with free oxide and the metal. Some occluded hydrogen is also present. A. Guntz and H. Bassett recommended using copper oxide freed from chloride and dried at 130°; they also said that no more than three grams should be made in one operation. G. T. Beilby and G. G. Henderson said that no nitride is formed unless the ammonia is present in large excess. J. J. Berzelius extracted cuprous oxide with a mixture of aq. ammonia and ammonium carbonate; in this way A. Guntz and H. Bassett transformed a sample with 83·82 per cent. nitride into one with 93 per cent. nitride. These workers also recommended using cuprous oxide in place of cupric oxide. Crystalline cuprous oxide acts more slowly than the precipitated oxide. They treated precipitated and dried cuprous oxide at 265° for two hours. They said that the reaction with the crystalline oxide begins at 270° and is very rapid at 310°. The nitride begins to decompose very near its temp. of formation so that the product is not very pure. A. Smits made copper nitride by the interaction of magnesium nitride and copper oxide and sulphate, but the product is very impure. E. B. Maxted tried heating cuprous oxide or chloride with lithium nitride, but the reaction is so violent that the copper nitride is decomposed and copper alone is obtained. According to F. F. Fitzgerald, when potassamide is added to a soln. of copper nitrate in liquid ammonia, an olive-green precipitate is formed, which is possibly $CuNH_2$ or Cu_2NH. When this product is dried in vacuo at 160°, it gives off nitrogen, but not ammonia, and forms cuprous nitride as a black, amorphous mass. A. C. Vournasos made **cupric nitride** by heating copper cyanide with ammonium nitrate: $3Cu(CN)_2+12NH_4NO_3=Cu_3N_2+6CO_2+14N_2+24H_2O$. Cuprous nitride is a very dark green powder which, according to A. Schrötter, is not decomposed by percussion or friction, but is decomposed into its elements when heated in air in the vicinity of 300°; and the reaction is accompanied by a red glow. If it be heated in oxygen decomposition occurs below 300°, and if in nitrogen, or carbon dioxide, above 300°. If the nitride is contaminated with cupric oxide, nitric oxide as well as nitrogen will be given off. A. Guntz and H. Bassett said that in carbon dioxide, the decomposition is complete at 600°; and if heated too rapidly, small explosions occur. J. J. Berzelius said that the nitride purified by the ammoniacal soln. decomposes at a lower temp. and with a slight explosion. F. F. Fitzgerald found that the nitride rapidly explodes when heated in air; and it is decomposed by water with a considerable evolution of heat. According to A. Schrötter, chlorine decomposes the nitride with the evolution of heat, and the formation of cupric chloride—A. Guntz and H. Bassett said cuprous chloride—and nitrogen; and with hydrogen chloride, cuprous and ammonium chlorides are formed. J. J. Berzelius said that with dil. acids, cuprous salts are formed and ammonia is evolved. According to A. Guntz and H. Bassett, the cuprous salt is formed quantitatively: $2Cu_3N+8HCl=6CuCl+2NH_4Cl$. The conc. acid dissolves the nitride rapidly, and the soln. on dilution precipitates cuprous chloride. F. F. Fitzgerald found that the nitride is completely soluble in hydrochloric acid, forming a colourless soln. According to A. Guntz and H. Bassett, if a little conc. sulphuric acid be poured on copper nitride, there is an energetic reaction, copper and cuprous oxide are formed and ammonium sulphate is produced without a loss of nitrogen. F. F. Fitzgerald said that sulphuric acid converts the nitride into an eq. quantity of copper and cupric sulphate. A. Schrötter said that sulphuric acid rapidly liberates nitrogen and leaves metallic copper behind; other non-oxidizing acids act similarly, but more slowly in proportion as they are more dil. Conc. nitric acid oxidizes the nitride with great violence; and, added A. Guntz and H. Bassett, scarcely half the nitrogen is transformed into ammonia; with dil. nitric acid, the action is less vigorous. Soln. of the alkali hydroxides have but a feeble action on the nitride in the cold; and even a boiling conc. soln. of sodium hydroxide requires an hour for a 10 per cent. decomposition: $2Cu_3N+3H_2O=3Cu_2O+2NH_3$.

Observations on *C. L. Berthollet's*[4] *l'argent fulminant* made by M. Faraday, L. A. Crell, B. Higgins, E. Murmann, N. W. Fischer, L. J. Proust, J. L. Gay Lussac, and M. H. Klaproth and F. Wolff have been discussed in connection with silver hydroxide (**3.** 22, 11). G. T. Beilby and G. G. Henderson found that when silver is heated in ammonia the physical structure of the metal is altered, but no nitride is formed. According to F. Raschig, the fulminating silver obtained by the action of aq. ammonia on silver oxide appears to have been **silver nitride,** Ag_3N, mixed with varying proportions of metallic silver. He obtained the product in a fairly pure state by treating silver oxide with 2 c.c. of ammonia in 25 per cent. aq. soln. per gram of oxide. When allowed to stand in the dark for 16–20 hrs., crystals of silver nitride separate out. The silver nitride may be also separated from the soln. by adding to the ammoniacal soln. ten times its vol. of alcohol; or by heating the soln. gently on a water-bath. The nitride is explosive, and it must not be disturbed until cold. The grey precipitate quickly darkens on standing, and it spontaneously decomposes into silver and nitrogen so that specimens usually contain some free silver. The nitride explodes easily and violently—particularly when dry. When treated with hydrochloric acid, the nitride is converted into ammonium and silver chlorides; with nitric acid, the conversion to ammonium and silver nitrates is complete. In the former case, the insolubility of the silver chloride hampers the reaction. Dil. sulphuric acid forms soluble ammonium and silver sulphates. Silver nitride is decomposed by a soln. of potassium cyanide: $Ag_3N+3KCy+3H_2O=NH_3+3KOH+3AgCy$. L. J. Olmer and M. Dervin found that silver ammonium fluoride decomposes below 160°, forming black silver nitride, Ag_3N, which is more unstable towards friction than towards temp. It sometimes explodes spontaneously between 140° and 160° after about 10 minutes, but below 140° it is more stable. It always explodes by contact or by a neighbouring detonation.

Nitrogen has no action on gold. G. T. Beilby and G. G. Henderson observed that no nitride is formed when gold is heated in ammonia, but the physical structure of the metal is much altered. The action of ammonia on gold oxide, resulting in the formation of fulminating gold, has been discussed in connection with gold oxide (**3.** 23, 14). According to W. R. Grove,[5] when water containing ammonium and auric chlorides is electrolyzed with a platinum anode and a gold cathode, a black substance is formed on the cathode. Its sp. gr. is 10·3, and when heated, it gives off 273 c.c. of nitrogen per gram. F. Raschig found that when conc. aq. ammonia is added to water containing aurous oxide in suspension, a black explosive powder, *aurous amminonitride,* $Au_3N.NH_3.(4H_2O)$, is formed; and this, when boiled with water, or dil. acids, furnishes **hemitrihydrated gold nitride,** $Au_3N.1\frac{1}{2}H_2O$. It is not decomposed by dil. nitric acid. If gold aurosoauric oxide be similarly treated, it forms a black *aurous amminotrihydroxynitride,* $Au_3N_2.3H_2O$, or $(AuOH)_3.N.NH_3$, which is very explosive when dry. Warm hydrochloric acid dissolves two-thirds the gold, and leaves one-third in the metallic state. When boiled with water, half the nitrogen is expelled, and **pentahydrated gold nitride,** $Au_3N.5H_2O$, is formed. It is not decomposed by boiling with dil. acetic, nitric, or sulphuric acid.

The metals of the alkaline earths all readily combine with nitrogen at a high temp., forming nitrides. F. W. Dafert and R. Miklauz[6] said that the reactions with calcium, strontium, and barium occur respectively at 410°, 380°, and 260°. According to H. Moissan, calcium is scarcely affected by nitrogen at ordinary temp., but when the temp. is raised a little, the surface of the metal becomes yellow and then bronze coloured. E. Biesalsky and H. van Eck studied the affinity of calcium for nitrogen; and C. Montemartini and L. Losana, the partition of oxygen and nitrogen, dry and moist, with calcium. According to H. Moissan, when calcium in an atm. of nitrogen is heated by a blast gas-flame, it forms a brown partly-sintered mass; it requires two hours' heating in an iron tube to complete the reaction. The product is **calcium nitride,** Ca_3N_2. I. I. Shukoff found the reaction is vigorous at 780° ; H. Herzer, and H. Hardtung worked at 900°. K. Kaiser obtained the nitride by the action of nitrogen on the heated sulphide. O. Ruff showed that calcium, when alloyed with more electropositive metals such as strontium, barium, sodium, or potassium, or with calcium nitride, combines more readily with nitrogen than pure calcium. From this observation it is concluded that the heteropolar nature of a metallic surface favours the combination with a homopolar gas, and from this it is assumed that it acquires influence charges from the surface valencies of the metal which determine its position and behaviour towards the surface. O. Ruff and co-workers added that the rate at which alloys rich in calcium absorb nitrogen depends on vol. relationship, temperature, potential of the added metal, and the calcium nitride content of the alloy. The contraction of calcium in the formation of calcium nitride keeps the exposed surface porous, but pure calcium is almost impassive towards nitrogen. Metals more strongly positive than calcium accelerate the adsorption (K, Ba) ; of the others, some have no effect (Mg, Pb, Sn), others retard it (As, Sb), and some inhibit it (Bi, Cu, Zn). The addition of more positive metals has a loosening effect on the valency electrons of calcium. Calcium nitride acts as a catalytic agent in all cases. With calcium alloys containing 5 per cent. of the nitride, pure argon can be obtained from atmospheric nitrogen in a few minutes even at a temp. below 320°. H. Erdmann made this nitride by mixing calcium shavings with liquid nitrogen. L. Maquenne, and J. Ferée obtained calcium nitride by heating calcium amalgam in a current of nitrogen. The amalgam was made by the electrolysis of conc. aq. soln. of the alkaline earth chlorides with a mercury cathode. The amalgam, in an iron or nickel boat, was heated to dull redness so as to drive off the mercury, and the temp. then raised to bright redness for a short time, and the nitride allowed to cool in the gas. Platinum is attacked by the metal. In any case the product is contaminated with free metal, and some of the material from the boat. H. Herzer gave 1250° for the temp. of decomposition. L. Maquenne made **strontium nitride,** Sr_3N_2, and also **barium nitride**, Ba_3N_2, by the method used for calcium nitride. He also obtained the nitride by heating in an atm. of nitrogen, calcium, strontium, or barium oxide or other salt with magnesium or another metal capable of reducing the oxide or salt employed. The product is contaminated with magnesia. C. Limb heated a mixture of barium fluoride and sodium in an atm. of nitrogen, and obtained barium nitride. D. Wolk made barium nitride by the action of nitrogen on heated barium amalgam. H. R. Ellis made the impure nitrides of the alkaline earths by igniting a mixture of the oxide and magnesium powder in air. G. Tammann said that the reaction occurs at 700°. H. Gautier prepared the nitrides of the alkaline earths by heating an alloy of cadmium and barium, strontium, or calcium in an atm. of nitrogen. The reaction begins at 600°. A. C. Vournasos found that barium cyanamide reacts with ammonium nitrate giving barium nitride; calcium carbide, with ammonium nitrate, or calcium with mercuric cyanide, giving calcium nitride: $3Ca(CN)_2+12NH_4NO_3=Ca_3N_2+6CO_2+14N_2+24H_2O$; and $3Ca+Hg(CN)_2=Ca_3N_2+Hg+2C$. A. Guntz and R. C. Mentrel prepared barium nitride by heating barium amide in vacuo above 400° ; the reaction is reversible : $3Ba(NH_2)_2 \rightleftharpoons 4NH_3+Ba_3N_2$—the amide is formed by heating barium in ammonia gas at 300°–380°. H. Hardtung said the reaction is not perceptible after half an hour's heating at 500°, but at 575°, 0·3 per cent. of nitrogen was absorbed from ammonia. A. Guntz found that barium hydride reacts with nitrogen at a red-heat, forming barium nitride. W. Borchers and E. Beck converted metals into nitrides by electrolyzing soln. of an oxide or a salt of the nitride-forming metal in a fused mixture of alkali or alkaline earth salt, using a cathode of molten metal which does not form a nitride readily, but readily alloys with the nitride-forming metal which is liberated at the cathode. The liquid alloy is treated with a current of nitrogen when the nitride is formed. The product is treated with water or steam when ammonia is evolved, and the oxide or hydroxide of the nitride-forming metal is returned to the electrolytic chamber. The process was tried with calcium, magnesium, and aluminium. When radium is exposed to moist air, E. Ebler said that some **radium nitride** is formed even more readily than in the corresponding case with barium.

H. Moissan found that under the microscope, calcium nitride appears in the form of transparent yellowish-brown crystals; and, according to L. Maquenne, barium nitride furnishes a bronze-brown crystalline mass, or else occurs in the form of yellow needles. H. Moissan gave 2·63 for the sp. gr. of calcium nitride at 17°; and *c.* 1200° for the m.p. F. Haber and G. van Oordt said that this compound melts and vaporizes at 900°. A. Guntz and R. C. Mentrel found that barium nitride does not melt at 1000°, but at that temp. it begins to volatilize. When ammonia is heated with barium nitride at higher temp., the gas is decomposed. H. Hardtung gave 700° for the temp. of formation of calcium nitride, and 1060° for the temp. of dissociation. C. A. Kraus and C. B. Hurd found the dissociation press. of calcium nitride to be of the order $0{\cdot}3\times10^{-4}$ to $5{\cdot}5\times10^{-4}$ cm. over the range 958° to 1049°, in agreement with 113·23 Cals. for the heat of formation. A. Guntz and H. Bassett gave for the heat of formation: $3Ca_{solid}+N_{2gas}=Ca_3N_{2solid}+112{\cdot}2$ Cals.; and A. Guntz: $3Ba_{solid}+N_{2gas}=Ba_3N_{2solid}+149{\cdot}4$ Cals. A. Guntz and F. Benoit gave for the heat of formation of calcium nitride, 37·1 Cals.; for strontium nitride, 31·8 Cals.; and for barium nitride, 31·3 Cals. E. Tiede and A. Schleede found that calcium and barium nitrides are rendered luminescent by active nitrogen. I. I. Shukoff found that the sp. electrical resistance of powdered calcium nitride exceeds 2×10^6 ohms. H. Moissan, H. Gautier, K. Kaiser, and F. Haber and G. van Oordt found that when calcium nitride is heated to about 600° in a stream of *hydrogen*, ammonia and calcium hydride are formed by a reversible reaction. On the other hand, H. Erdmann and H. van der Smissen found that calcium nitride gives no perceptible ammonia when heated in hydrogen between 500° and 800°; F. Haber and G. van Oordt studied the production of ammonia by passing hydrogen over calcium nitride at 600°; and H. Hardtung obtained only about one per cent. of ammonia by allowing hydrogen to act on calcium nitride between 350° and 760° for about an hour. C. A. Kraus and C. B. Hurd found that in the system consisting of calcium, calcium hydride, and calcium nitride, an equilibrium was established near 1000° and only hydrogen was present in the gas phase. The hydrogen was ultimately all absorbed at 870°. For addition compounds with hydrogen, *vide infra*, calcium amide. According to H. Moissan, when calcium nitride is heated in *air*, it oxidizes with incandescence; and in *oxygen* oxidation begins below red-heat, and then continues without a further application of heat. L. Maquenne found that *water* decomposes these nitrides with the evolution of ammonia, *e.g.* $Ba_3N_2+6H_2O=2NH_3+3Ba(OH)_2$; alcohol has no action, but H. Moissan found that calcium nitride and absolute *alcohol*, when heated in a sealed tube, furnish ammonia; and calcium ethoxide and *ethyl chloride* at dull redness slowly form calcium chloride and carbide, and methane. Calcium nitride is decomposed by *chlorine* in the cold, and the mass becomes incandescent; similarly also with *bromine* vap.; while *iodine* acts vigorously at dull red-heat. C. Montemartini and L. Losana found that *hydrogen chloride* passed over heated calcium nitride forms calcium chloride and ammonia. Conc. *acids* decompose calcium nitride slowly, or not at all, while dil. acids act vigorously, forming calcium and ammonium salts—no gas is evolved if the nitride is pure. *Sulphur* reacts with calcium nitride at 500°, forming calcium sulphide. Contrary to R. C. Mentrel, C. A. Kraus and C. B. Hurd observed no indication of the absorption of *ammonia* by calcium and barium nitrides. According to C. Montemartini and L. Losana, *nitrogen peroxide* oxidizes the nitride slowly at a red-heat, and at a higher temp., the reaction is very vigorous, and nitrogen is evolved. Calcium nitride and *phosphorus*, at a red-heat, form calcium phosphide. At 600°, *carbon* has no action on calcium nitride, but in an electric furnace, calcium carbide is formed; at 1200°, in an atm. of nitrogen, calcium cyanide is formed. L. Maquenne observed a similar reaction with barium nitride, resulting in the formation of barium cyanide; and a similar product is obtained by the action of *carbon monoxide:* $Ba_3N_2+2CO=Ba(CN)_2+2BaO$—*vide infra,* magnesium nitride. The reaction is interesting, since it furnishes a method of fixing nitrogen as cyanide by heating a mixture of barium oxide and carbon in nitrogen. H. Hardtung found no cyanogen in the exit gases when carbon dioxide or monoxide acts on calcium nitride between 760° and 1000°, but a trace of cyanide was found in the residue. According to H. Moissan, *silicon* and *boron* have no action on calcium nitride at 100°; and *sodium, potassium,* and *magnesium* have no action at a red-heat. According to O. Schmidt, *sodium carbonate,* carbon, and calcium nitride form sodium cyanide at a red-heat: $Ca_3N_2+Na_2CO_3+C=2NaCN+3CaO$, a reaction which continues without the further application of heat.

According to A. C. Vournasos,[7] beryllium does not react with nitrogen or ammonia at an elevated temp., but **beryllium nitride,** Be_3N_2, can be made by heating beryllium in cyanogen at 800°. He also found that beryllium reacts quantitatively with the cyanides to form the nitride: $3Be+Hg(CN)_2=Be_3N_2+Hg+2C$. F. Fichter and E. Brunner observed that beryllium absorbs nitrogen from 900° upwards, but only a surface layer is formed, so that it is necessary to powder the product and repeat the process many times, in the course of which much oxide is formed. A better result is obtained by using ammonia. In both cases, the product has the formula Be_3N_2. Beryllium nitride is amorphous, but may be fused if heated rapidly to 2200° in nitrogen under atm. press., and then solidifies to colourless crystals, which scratch glass. It dissociates at 2400°. The chemical properties are similar to those of aluminium nitride. The compound is stable in air, and is only slowly decomposed by boiling water. Dil. acids and hot conc. soln. of alkali hydroxides decompose it more readily than aluminium nitride. The nitride is usually decomposed more readily than aluminium nitride. The nitride usually contains a little carbon, formed by the reaction $3Be_2C+2N_2=2Be_3N_2+3C$. Direct experiment shows that beryllium carbide absorbs nitrogen at 1250°, or reacts with ammonia at 950°–1000°, liberating carbon. A mixture of beryllia and carbon yields the nitride at 1900° in nitrogen. Cyanamide compounds are not formed.

In 1857, H. St. C. Deville and H. Caron noticed that when magnesium is distilled in air, the product is sometimes covered with small, colourless, acicular crystals which were quickly destroyed by moisture, forming magnesia and ammonia. These crystals were very probably those of **magnesium nitride,** Mg_3N_2. F. Briegleb and A. Geuther made this compound by heating magnesium in a current of ammonia or nitrogen; *e.g.* magnesium filings, in a porcelain boat, were heated to bright redness in a current of dry, acid-free nitrogen quite free from air. Some silicon is present as impurity being reduced from the silicates of the porcelain-boat; but, by using an old boat, they obtained a product almost free from that impurity. H. Hardtung found that the reaction begins at about 450°, and proceeds rapidly at 600°. A. Rossel, and G. Tammann made some observations on this subject. E. Biesalsky and H. van Eck studied the affinity of magnesium for nitrogen; and C. Montemartini and L. Losana, the partition of nitrogen and oxygen, dry or moist, between magnesium. V. Merz found the use of a very high temp. to be neither necessary nor desirable. Combination readily occurs in a glass tube heated by a gas burner. The glass is blackened during the operation owing to the liberation of silicon. A. Geuther obtained the nitride mixed with silicon by heating magnesium silicide in a current of nitrogen; and K. Kaiser, by the action of nitrogen on the heated sulphide, or the molten chloride. A. Smits, and S. Paschowetsky said that a current of ammonia acts better than one of nitrogen. A. Smits obtained the nitride by burning magnesium powder in a crucible while stirring with an iron rod; J. W. Mallet, by heating magnesium in a crucible with insufficient air for combustion to the oxide; and W. Kirchner, by burning a cylinder of magnesium, heated by a bunsen burner, in air. According to W. Eidmann and L. Möser, magnesium nitride can be prepared by heating in air magnesium powder mixed with a number of oxides of metals which readily oxidize and also by heating with certain metals and carbides. A mixture of equal parts of iron and magnesium, heated in an uncovered crucible, gave a crude product containing 36 per cent. of the nitride. By heating magnesium powder strongly in a covered crucible with a minute opening in the cover, a lower layer of nitride is formed, covered with unchanged magnesium, and a surface layer of oxide. By carefully regulating the conditions, as much as 78–80 per cent. of nitride can be obtained in the product, a value approaching very nearly to that required for a complete absorption of the oxygen and nitrogen of the air (calc. 82·3 per cent.). E. C. Szarvasy obtained the nitride by heating a mixture of graphite in an atm. of hydrogen, and then stirring the hot mixture in air ; H. Mehner, and W. Neuberger, by heating in an electric furnace a mixture of magnesia and carbon in an atm. of nitrogen ; and K. Kaiser, by passing nitrogen over magnesium hydride: $3MgH_2+2N_2=Mg_3N_2+2NH_3$; and reconverting the nitride into hydride: $2Mg_3N_2+9H_2=6MgH_2+4NH_3$. This gives a cyclic process for the fixation of nitrogen. W. Borchers and E. Beck also observed a cyclic process in which a magnesium alloy was obtained from magnesia, etc.—*vide supra*, alkaline earths. H. Hardtung heated magnesium for two hours in an atm. of ammonia, and found at different temp. the amounts absorbed to be those indicated in Fig. 12. He gave 600° for the temp. of formation, and 900° for the temp. of dissociation. H. Herzer gave 1150° for the decomposition temp.; and 1·829 to 1·872 for the sp. gr. at 25°/4°. This makes the mol. vol. between 53·9 and 56·2. W. Eidmann observed the formation of magnesium nitride when a mixture of magnesium and nitrogenous substances is heated to redness, and when magnesium is heated with boron and silicon nitrides, or the cyanides of the alkali metals, the alkaline earth metals, copper, zinc, cadmium, lead, nickel, and cobalt. A. C. Vournasos also found that magnesium reacts violently with the thiocyanates, and more quietly with the cyanides, forming the nitride : $2KCN+3Mg=Mg_3N_2+2K+2C$.

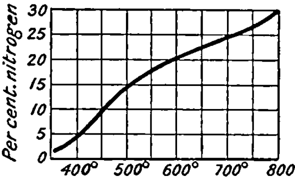

FIG. 12.—The Absorption of Nitrogen by Magnesium.

A. Remelé observed the photoelectric effect with magnesium nitride; and R. W. Riding and E. C. C. Baly studied the action of cathode rays on magnesium nitride. I. I. Shukoff found that the electrical resistance of powdered magnesium nitride exceeds 2×10^6 ohms. Magnesium nitride is a greenish-yellow, amorphous mass, which when heated, becomes yellowish-brown. N. Whitehouse found that it is not reduced by dry *hydrogen* free from oxygen, but with water-gas, magnesia, carbon, cyanamide, and other products are formed. K. Kaiser, however, represented the reaction : $Mg_3N_2+6H_2=3MgH_2+2NH_3$, and H. Hardtung obtained about 3 per cent. of ammonia by this reaction at temp. between 20° and 760° during an hour's run. F. W. Dafert and R. Miklauz observed no tendency of magnesium nitride to form addition products analogous to those with calcium and lithium nitrides. F. Briegleb and A. Geuther found that magnesium nitride is oxidized slowly to magnesia, when heated in *air;* and in dry *oxygen*, it burns with incandescence. Moist air decomposes it, and the exposed product smells of ammonia. The action of *water* is vigorous, resulting in the formation of ammonia and magnesium hydroxide. J. Lipsky studied the fixation of nitrogen by converting it into ammonia *viâ* magnesium nitride as intermediary. E. A. Schneider said that *chlorine* readily reacts with the nitride, forming magnesium and ammonium chlorides. C. Montemartini and L. Losana found that *hydrogen chloride* when heated with magnesium nitride forms the chloride and ammonia. F. Briegleb and A. Geuther found that the nitride readily reacts with conc. or dil. *hydrochloric acid*, forming magnesium and ammonium chlorides ; *hydrogen sulphide* furnishes magnesium and ammonium sulphides ; and, according to S. Paschkowetsky, the nitride is scarcely attacked by conc. *sulphuric acid* in the cold, but when heated, sulphur dioxide is evolved. F. Briegleb and A. Geuther found conc. and dil. *nitric acid* furnish magnesium and ammonium nitrates; *phosphorous chloride* gives phosphorus nitride, and, added E. A. Schneider, the reaction is vigorous at a red-heat—phosphorus distils off, the mass becomes white-hot, and the residue contains magnesium chloride and phosphorus—not magnesium phosphide. F. Briegleb and A. Geuther said that *phosphoryl chloride* can be distilled from the nitride without change, but at 170° in a sealed tube, it forms a dark-coloured mass with metaphosphoric acid in the aq. soln. Magnesium nitride is decomposed when heated to bright redness in an atm. of *carbon monoxide:* $Mg_3N_2+3CO=3MgO+2CN+C$; and likewise also with *carbon dioxide:* $2Mg_3N_2+3CO_2=6MgO+2CN+C+N_2$. These reactions have been questioned by F. Fichter and C. Schölly, who, working at 1250°, observed no formation of cyanogen, and represented the reactions: $Mg_3N_2+3CO=3MgO+N_2+3C$; and $Mg_3N_2+3CO_2=3MgO+3CO+N_2$. H. Hardtung obtained traces of cyanogen in the gas with both carbon monoxide and dioxide between 760° and 1000°; but no cyanides were found in the residue. Carbon monoxide did not react appreciably at 750°, and even at higher temp. is less reactive than the dioxide. F. Briegleb and A. Geuther observed no reaction between magnesium nitride and *alcohol* or *ethyl iodide* at 160°; A. Smits observed no change with absolute alcohol at 140°–160°; nor did an alcoholic soln. of *glycerol* or *oxalic acid* have any action, but a soln. of *urea* did change the nitride. S. Paschkowetzky found the nitride has very little action on *phenol, triphenyl phosphate, benzoyl chloride,* and *benzoic anhydride.* O. Schmidt found that *alkali carbonates* react with magnesium nitride as they do with other nitrides. A. Smits reported that magnesium nitride with *nickel chloride* yields a black substance which forms with acids a green soln. which contains some ammonia; *cobalt chloride,* and *ferric and ferrous chlorides* behave similarly, but the acid soln. has no ammonia; *silver, mercury,* and *chromium chlorides* form nitrides which are decomposed by water giving off ammonia; *platinic chloride* gives metallic platinum; and *cupric oxide or sulphate* gives copper and its nitride. There is a vigorous reaction with *lead dioxide,* and *ferrous or ferric oxide.*

K. Iwase[8] found that nitrogen is not dissolved by zinc. W. R. Grove reported what was possibly impure **zinc nitride,** Zn_3N_2, to be formed by the electrolysis of water with ammonium chloride in suspension by an anode of zinc and a cathode of platinum wire. The spongy mass collecting about the zinc rod was washed and dried. Its sp. gr. was 4·6, and it conducted electricity. When ignited, nitrogen and some hydrogen were evolved. H. N. Warren also claimed to have made zinc nitride by the electrolysis of soln. of zinc salts in presence of ammonium salts. H. Pauli could not make a nitride with a current density of 1·5–29·12 amp. per sq. m. E. Frankland said that zinc amide at a dull red-heat forms a mixture of zinc and zinc nitride. According to P. Herrmann, when zinc-dust is heated in ammonia, two compounds are formed: (i) At 500°, a grey *zinc mononitride,* ZnN, appears. It is decomposed by water slowly at ordinary temp., and rapidly when heated, forming ammonia and zinc hydroxide. With acids the mononitride develops nitrogen, and traces of hydrogen and ammonia. (ii) At 400°, a brown substance is produced in small quantities. It does not decompose boiling water, and it contains less nitrogen than the mononitride. It reacts similarly with acids. G. F. Hüttig, H. Herzer, and A. H. White and L. Kirschbraun prepared zinc nitride by passing ammonia over zinc powder at 600°. The black nitride so obtained decomposed slowly into its elements at the temp. used for its formation so that the product was always contaminated with zinc. The composition indeed depended on its speed of formation. They regarded their product as a solid soln., $Zn_3N_2.nZn$. G. G. Henderson and co-workers confirmed these results. H. Hardtung heated zinc-dust in ammonia gas at different temp. for half an hour, and found the zone of stability to be rather narrow as indicated by the curve, Fig. 13.

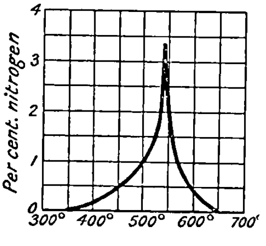

FIG. 13.—The Formation of Zinc Nitride from Zinc and Ammonia.

E. Frankland obtained zinc nitride by heating the amide to 200°, thus $3Zn(NH_2)_2=Zn_3N_2+4NH_3$; A. C. Vournasos, by heating zinc cyanide with ammonium nitrate: $3Zn(CN)_2+12NH_4NO_3=Zn_3N_2+6CO_2+14N_2+24H_2O$; and W. J. Bently and P. L. Stern, by passing ammonia—freed from oxygen and moisture—over zinc-dust—previously washed with a soln. of ammonia and ammonium chloride, alcohol, and ether, and dried in vacuo—for 30 minutes at 650°, and the product cooled below 200° before exposing it to air. The highest yield was 36·8 per cent. nitride. O. Ravner observed the formation of zinc nitride during the distillation of zinc. L. Arons made the nitride by the action of an arc between zinc poles in an atm. of nitrogen; and F. Fischer and F. Schröter, by the arc process illustrated by Fig. 11. A. Rossel found that the nitride is formed by heating a mixture of calcium carbide and powdered zinc at a red-heat. Zinc nitride prepared by the amide process is a green powder, that prepared by other processes is black. E. Frankland said that zinc nitride is decomposed by water, forming ammonia and zinc hydroxide; and with dil. acids, ammonium and zinc salts are formed. W. R. Grove prepared what seemed to be **cadmium nitride,** Cd_3N_2, by the same process as that employed for zinc nitride. It was also prepared by F. Fischer and co-workers by the method of Fig. 14; and G. S. Bohart obtained it as an orange-coloured powder by heating cadmium amide in vacuo at 180°. The black powder exploded when heated. With acids, cadmium and ammonium salts are formed. G. G. Henderson and J. C. Galletly found that cadmium behaved like zinc when heated in ammonia. P. Herrmann found that when cadmium is heated in ammonia, at about 750°, a yellow oil distils over; at 1000°, cadmium oxide is reduced by ammonia to the metal. Cadmium does not absorb nitrogen at 1000°.

J. J. Thomson and R. Threlfall[9] noticed that when an electric discharge is passed through nitrogen gas confined over mercury, there is a diminution in pressure; this was at one time attributed to the formation of a polymerization of the mol.—possibly to N_3. The phenomenon was afterwards found to arise from the union of nitrogen with mercury, probably forming mercury nitride—*vide infra.* P. Plantamour passed dry ammonia over dry but freshly prepared, yellow mercuric oxide, first in the cold, and later at 150°, and obtained an explosive substance thought to be impure **mercuric nitride,** Hg_3N_2. The product always contains some globules of mercury—even though it has been heated above 120°; the mercury may be removed by cold dil. nitric acid, and the nitride then washed and dried. If ammonia is passed over mercuric oxide—previously heated to 100°–200°—a dark grey mixture of mercury, mercurous oxide, and a small quantity of mercury nitride are formed, which, when treated with dil. nitric acid furnishes, besides mercury, cinnamon-brown curdy flakes of what was thought to be a compound of mercury nitride and nitrate. C. H. Hirzel said that mercuric oxide dried at 160° is not attacked by ammonia at 150°. H. N. Warren worked at 200°, and C. H. Hirzel repeated P. Plantamour's work, but exposed the mercuric oxide at 40°–50° to the action of the ammonia, and afterwards not over 100°; he obtained a product corresponding with mercuric nitride. T. Weyl, and H. Gaudechon said that C. H. Hirzel's product always contains oxygen, and is really dimercuriammonium oxide, $(NHg_2)_2O$—*q.v.* This substance at 125°, in contact with ammonia, forms mercuric nitride: $3(NHg_2)_2O+2NH_3=4Hg_3N_2+3H_2O$, which is associated with small globules of mercury and is like P. Plantamour's product. There is therefore some doubt as to whether the product obtained by the action of ammonia on mercuric oxide contains unchanged mercuric oxide or is a definite oxygenated compound. K. A. Hofmann and E. C. Marburg, and H. Gaudechon believe that mercuric nitride cannot be obtained by this mode of preparation. E. C. Franklin reported mercuric nitride of a high degree of purity to be formed on adding a soln. of mercuric iodide or bromide to an excess of a soln. of potassium amide in liquid ammonia: $3HgI_2+6KNH_2=Hg_3N_2+6KI+4NH_3$. The chocolate-coloured precipitate becomes darker on standing and is then more easily washed with liquid ammonia. The nitride is said to be very explosive and to require handling with great care.

Mercuric nitride of undetermined composition was stated by R. Threlfall to be formed as a brown film by the action of nitrogen on mercury when the gas under diminished press. is under the influence of an electric discharge ; and R. J. Strutt found that activated nitrogen reacts with mercury, forming a nitride. F. Fischer and F. Schröter also prepared the nitride by the process indicated in connection with Fig. 11. O. Flaschner found that scarcely any hydroxylamine is reduced by the mercury cathode.

P. Plantamour said that the impure mercury nitride, which he prepared, exploded with a white flame having a bluish-purple border when heated, when struck by a hammer, or when rubbed with a glass rod on a watch-glass. In the last case, the glass was perforated with a round hole. The explosion is said to be almost as violent as that of nitrogen iodide. According to C. H. Hirzel, mercury nitride exposed to *air* forms a dirty-white, non-explosive powder which effervesces feebly with acids : *water* slowly transforms the nitride into a white powder. E. C. Franklin's preparation exploded in contact with water, owing possibly to the presence of a trace of potassium amide. Dry *carbon dioxide* does not act on the dry nitride, but it forms with the moist powder a white substance containing carbon dioxide. E. C. Franklin said that the nitride can be dissolved in dil. *acids*. C. H. Hirzel said that conc. *nitric acid* colours the compound yellow, and then white, while dil. nitric acid transforms it into a white powder—slowly when cold, rapidly when heated. P. Plantamour found that conc. nitric acid at 40° can be made to dissolve the nitride, forming a soln. of ammonium and mercuric nitrates ; *hydrochloric acid* forms a soln. of ammonium, mercuric, and mercurous chlorides ; and boiling dil. *sulphuric acid*, a soln. of ammonium and mercuric sulphates together with a little yellow basic sulphate. The substance also explodes when brought in contact with sulphuric acid, and in that case a white powder remains behind. When heated with *potassium hydroxide*, ammonia gas is evolved, and mercury sublimed ; and C. H. Hirzel said that a cold soln. of potassium hydroxide acts slowly, and a boiling soln. rapidly forms a yellow powder, and ammonia is gradually evolved. E. C. Franklin said that the nitride is soluble in liquid *ammonia*, but not if potassium amide be also present. C. H. Hirzel found that cold aq. ammonia decomposes the nitride, forming a yellow powder ; *ammonium carbonate* acts rapidly, forming a yellow and then a white powder ; an aq. boiling soln. of *ammonium chloride* slowly dissolves the nitride with the evolution of ammonia ; and a soln. of *mercuric chloride* transforms it into a reddish-brown powder. P. Plantamour found that if mercury nitride be carefully mixed with *cupric oxide* and heated, nitrogen gas is evolved, mercury is formed, but no water.

W. H. Balmain[10] first prepared **boron nitride**, BN, by the action of molten boric acid on potassium cyanide. He considered the product of the action resembled cyanogen, and was able to unite with the metals to form compounds analogous to the cyanides, and he named the radicle *ethogen*—from αἰθός, brilliant—in allusion to its appearance in the oxidization zone of a flame. Later on, W. H. Balmain recognized that he was mistaken in assuming that ethogen is like cyanogen in forming compounds with the metals. R. Warington believed that traces of boron nitride occur in the ammonium chloride found in some volcanic districts, and assumed that it was formed from boric acid. H. St. C. Deville and F. Wöhler reported that when amorphous boron is heated to a moderate temp. in air, the boron takes fire and burns completely. The product was not all boric oxide, but rather a mixture of boron oxide and nitride. The microscopic crystals occurring in the mixture were probably those of boron nitride, for, when heated with soda-lime, they gave off ammonia. They also obtained the same substance by heating a 4 : 1 mixture of boric oxide and carbon in a current of nitrogen. W. Hempel found that under these circumstances the yield is greater if the press. be increased, thus, in 15 mins. at ordinary press., 0·014 grm. of the nitride was obtained from 3 grms. of boric acid and 2 grms. of carbon ; at 25 atm. press., 0·019 grm. ; and at 66 atm. press., 0·032 grm. H. Moissan showed that amorphous boron does not unite with nitrogen at 900°, but at 1200°, boron nitride is readily formed. E. Friederich and L. Sittig, and H. Mehner obtained it by heating a mixture of boric oxide and carbon in an atm. of nitrogen. K. Kaiser made boron nitride by the action of nitrogen on the heated sulphide. H. St. C. Deville and F. Wöhler obtained the nitride by heating amorphous boron at a dull red-heat in dry ammonia—the reaction proceeds with incandescence, and hydrogen is evolved. L. Möser and W. Eidmann heated boric oxide to 800° in a current of ammonia: $B_2O_3+2NH_3=2BN+3H_2O$; the crust of nitride which forms on the surface of the grains hinders the reaction, but if the boric oxide be mixed with twice its weight of calcium phosphate, the reaction proceeds rapidly in a blast gas-furnace. The calcium phosphate is removed by washing with a little very dil. hydrochloric acid. F. Wöhler obtained the nitride by heating a mixture of ammonium chloride and borax, and, according to H. Rose, boric oxide may be used—ammonium nitrate is not suitable. L. Möser and W. Eidmann represented the reaction: $2NH_4Cl+Na_2B_4O_7=2NaCl+2NH_3+2B_2O_3+H_2O$, and, at a higher temp., the ammonia reacts with the boric oxide; $B_2O_3+2NH_3=2BN+3H_2O$. They said that it is better to heat a mixture of borax with an inert substance like calcium phosphate so as to obtain a porous mass, and heat the product in the vap. of ammonium chloride. The calcium phosphate is removed by washing with a little very dil. hydrochloric acid. F. Meyer and R. Zappner found that the above-described processes gave very poor yields, and the only satisfactory method is to heat the boron amminochloride in a quartz glass tube, at 500°–600°, and finally at 1000° in a current of hydrogen charged with the vap. of boron trichloride and ammonia, when ammonium chloride and boron nitride are formed. The yield was 80–86 per cent. H. Davy showed that amorphous boron inflames when heated in dry nitrous oxide, and H. St. C. Deville and F. Wöhler represented the reaction with nitric oxide: $5B+3NO=B_2O_3+3BN$. The reaction proceeds *mit blendender Feuererscheinung*; but if crystalline boron be employed no reaction occurs at the softening temp. of hard glass. A. C. Vournasos showed that when boron is heated in cyanogen or hydrogen cyanide, the nitride is formed, and the same product is obtained by adding finely divided boron to fused potassium cyanide.

The potassium cyanide is first melted in a porcelain crucible at 650° in the absence of air, and poured out on a marble slab. It is then remelted in a clay or porcelain crucible, and the dry, finely-powdered element added in portions, the mixture being agitated from time to time, and the heating continued for fifteen minutes after the final addition. The cooled black mass is placed in warm water, and the insoluble residue of nitride and amorphous carbon is carefully and gently ignited in air to remove the carbon.

Boron, as an impalpable powder, reacts with many organic substances containing nitrogen—*e.g.* thiocarbamide, potassium or ammonium thiocyanate, etc.—*vide infra*, aluminium nitride. F. Wöhler obtained boron nitride by calcining a mixture of borax and anhydrous potassium ferrocyanide; W. H. Balmain used a mixture of boric acid and potassium cyanide, mercuric cyanide, cyanogen sulphide, or mellone; and M. Darmstadt, a mixture of boric oxide and urea. N. Whitehouse obtained it by heating boric oxide with carbon or carbon and iron in the presence of nitrogen; boric oxide does not form the nitride when heated in an atm. of hydrogen and nitrogen gases. C. A. Martius prepared the nitride by calcining boron amminotrichloride; A. Stock and W. Holle, from boron amminobromide; G. Gustavson, a mixture of ethylamine and boron trichloride at 200°; and A. Stock and M. Blix, boron imide, or boron imidochlorohydrate at 130°. S. Peacock obtained boron nitride by heating the oxide in an atm. of nitrogen and adding sodium when the temp. necessary for reaction is attained.

Boron nitride is a voluminous white powder which under the microscope shows no sign of crystallization. The sp. gr. depends on the temp. to which it has been ignited. F. M. Jäger and H. G. K. Westenbrink said that the X-radiogram shows that the space-lattice is either cubic with $a=7{\cdot}44$ A., or tetragonal with $a=4{\cdot}295$ A., and $c=5{\cdot}176$ A., or $a:c=1:1{\cdot}2052$. In the first case, the elementary cell contains 20 molecules, which is improbable; and in the second case, 4 or 5 molecules. The crystals were also examined by G. Hassel, who found them to be hexagonal and nearly the same as those of graphite. W. Hume-Rothery discussed the electronic structure. E. Friederich and L. Sittig said that the crystals are not cubic; the sp. gr. is 2·34; H. Herzer gave 2·321 at 25°/4°. V. M. Goldschmidt gave 2·255; and he found that the optically trigonal or hexagonal crystals have the index of refraction 1·74; and birefringence 0·3. The optical character is negative. The basal cleavage is good. The hardness is 1 to 2. The nitride melts at 3000° under press., and sublimes before melting; the electrical resistance at ordinary temp. and at the m.p. is very large. The great infusibility of boron nitride, said J. Boeseken, indicates a high degree of polymerization. L. Möser and W. Eidmann said that if the nitride be prepared at a very low temp., it appears like a colourless gelatine which dries to a hard, brittle mass which enters into reactions more readily than other forms. Thus, A. Stock and M. Blix consider that there are two forms—one much more sensitive than the other to chemical reactions; that prepared from the imide or imidochlorohydrate at 130° is an example, and if this be heated in a crucible by a blast gas-flame, it becomes insensitive to chemical action. F. Meyer and R. Zappner said the stability towards water depends on the temp. to which the nitride has been ignited. F. Wöhler said that it is stable at a high temp., and W. H. Balmain added that it is infusible. A. Magnus and H. Danz gave $2{\cdot}5153+0{\cdot}0063096(\theta-22)-0{\cdot}0_{5}32885(\theta-22)^{2}$ to represent the mol. ht. of boron nitride between 400° and 900°. R. E. Slade and G. I. Higson found that the dissociation press. of the nitride, at 1222°, is 9·4 mm.; and the heat of formation, about 69 Cals. W. Jevons attributed the bands in the spectrum of boron chloride with a little nitrogen to boron nitride; R. S. Mulliken, to boron oxide. W. Jevons also found the boron nitride bands in the arc spectrum of boron in air. W. H. Balmain discovered that boron nitride glows with a green light when held in the edge of a flame; F. Wöhler ascribed the phenomenon to the slow oxidation of the nitride. E. Tiede and F. Büscher said that only when free boric oxide is present is the nitride luminescent in the flame. The luminescence is not due to oxidation but is physical in its origin. The cause of the activation is unknown. E. Tiede and H. Tomaschek said that boron nitride exhibits luminescence only when small quantities of carbon are present. E. Tiede and A. Schleede observed that the nitride, when in contact with active nitrogen, and sensitized by flame, is phosphorescent. F. Wöhler said that boron nitride suffers no change when heated to redness in *hydrogen;* and that it does not ignite or burn when heated in *air;* but in *oxygen,* if at a high enough temp., it burns with a greenish-white flame and gives off the vap. of boric oxide. F. Wöhler, M. Darmstadt, W. H. Balmain, and L. Möser and W. Eidmann observed that in a flame the nitride phosphoresces with a greenish-white light, and oxidizes very slowly; the thermo-luminescence is hindered when much boric oxide is present. A. Remelé found that boron nitride exhibits the photoelectric effect. F. Wöhler said that *hydrofluoric acid* attacks the nitride quickly, forming ammonium fluoborate; and, added L. Möser and W. Eidmann, if the nitride be heated with *ammonium fluoride* and an excess of conc. sulphuric acid, it is completely decomposed into ammonium sulphate and boron trifluoride. According to F. Wöhler, and M. Darmstadt, *chlorine* at a moderate heat has no action, but if heated more strongly boron trichloride is formed. N. Whitehouse showed that dry *hydrogen chloride* at 1470° does not attack boron nitride; but C. Montemartini and L. Losana found that all the nitrogen is thus converted to ammonia, and boron chloride is formed. M. Darmstadt said that *hydrochloric acid* heated in a sealed tube with boron nitride at 160°–200°, forms boric acid and ammonium chloride quantitatively; but he found that *iodine* at a red-heat does not attack the nitride. L. Möser and W. Eidmann said that *sulphur dioxide* is partly reduced to sulphur by boron nitride, and F. Wöhler showed that hot conc. *sulphuric acid* slowly forms ammonium sulphate. A. Stock and M. Blix showed that the nitride formed at low temp. is rapidly dissolved by aq. *ammonia,* but not the nitride which has been calcined. F. Wöhler said that the nitride is not changed at a red-heat in an atm. of *carbon dioxide*, but L. Möser and W. Eidmann showed that the carbon dioxide is partly reduced to carbon monoxide—the boric oxide simultaneously formed as a film protects the nitride from further action. The vap. of *carbon disulphide* does not alter the nitride at a red-heat. M. Wunder and B. Jeanneret found that boron nitride is opened up when the powder is heated with *phosphoric acid* of sp. gr. 1·75. F. Wöhler showed that boron nitride acts as a reducing agent, in that molten *chromic anhydride* is reduced to chromic oxide; *molybdic anhydride*, to blue oxide; *arsenic trioxide*, to arsenic; *antimony trioxide*, to antimony; *lead*, *copper*, and *mercuric oxides*, to the metals with the formation of nitric oxide or nitrogen peroxide; and *bismuth and cadmium oxides* form a borate and nitric oxide and the latter yields some cadmium. *Zinc and ferric oxides* are not attacked. U. Sborgi and A. G. Nasini prepared nitric oxide (*q.v.*) by the action of boron nitride on *iron, copper, manganese, nickel, and cobalt oxides*. *Lead nitrate* forms lead borate. An aq. soln. of *potassium hydroxide*, said F. Wöhler, does not attack boron nitride, but with molten alkali there is a rapid evolution of ammonia. The nitride prepared at a low temp. was found by A. Stock and M. Blix to be rapidly attacked by hot dil. alkali-lye, but not so with the nitride which had been heated to a high temp. L. Möser and W. Eidmann found that when melted with *sodium dioxide*, boron nitride is converted to a borate and nitrate; and when the powdered nitride is added to the molten dioxide, there is an evolution of nitrogen and the formation of a borate with incandescence. A. C. Vournasos heated boron nitride with *sodium formate* and obtained amorphous boron, hydrogen, ammonia, and a boron hydride. F. Wöhler found that when heated with *potassium carbonate*, potassium borate and cyanate are formed: $BN+K_2CO_3=KBO_2+KOCN$; if the nitride be in excess, some potassium cyanide is formed. J. R. Morse patented a process for heating a mixture of boron nitride and potassium carbonate to dull redness whereby potassium cyanide was formed: $4BN+3K_2CO_3+2C=K_2B_4O_7+CO_2+4KCN$; if the mass be mixed with iron filings, alkali ferrocyanide is formed. W. H. Balmain, J. C. G. de Marignac, and H. St. C. Deville and F. Wöhler were not able to prepare compounds of boron nitride with the *metals*. A. Stähler and J. J. Elbert discussed a method of "fixing" the nitrogen of the atmosphere through the agency of the boron nitrides.

According to F. Briegleb and A. Geuther,[11] **aluminium nitride,** AlN, is formed by heating aluminium turnings in a hard glass tube in an atm. of nitrogen. F. Fichter and G. Oesterheld said that aluminium begins to absorb nitrogen at 750°. F. Fichter worked at 720°–740°, and in order to effect complete nitridation, he recommended finely powdering the product, and repeating the operation. J. Wolf said that the process works much more satisfactorily at 820°, and F. Fichter and A. Spengel added that the reaction started at 800° quickly rises in temp. to 1300°. N. Tschischewsky said the reaction starts at 400°, and is rapid at 1350°. Impurities may be removed by heating the product to redness in a current of dry hydrogen chloride. K. Iwase studied the solubility of nitrogen in aluminium; E. Biesalsky and H. van Eek, the affinity of nitrogen for aluminium; and C. Montemartini and L. Losana, the partition of dry or moist oxygen and nitrogen between aluminium. A. H. White and L. Kirschbaum prepared the nitride by heating aluminium to 700° in a current of ammonia. I. I. Shukoff said the reaction is vigorous at 780°. H. Moissan found aluminium nitride to be present in some commercial samples of aluminium; and L. Frank and A. Rossel, A. Rossel, E. Kohn-Abrest, and C. Matignon noted that it is formed during the oxidation of aluminium in air. H. R. Ellis obtained the impure nitride by igniting a mixture of alumina and magnesium powder in air. C. Zenghelis said that the nitride is formed if aluminium be burnt in oxygen and a current of nitrogen be substituted for oxygen while the metal is burning. L. Arons obtained it by heating aluminium by an electric current in an atm. of nitrogen. J. W. Mallet observed that by heating aluminium white-hot in a carbon crucible yellow flecks of aluminium nitride are formed. A better yield of nitride is obtained if the aluminium be bedded in sodium carbonate in a graphite crucible and heated for four or five hours. Part of the aluminium is oxidized to alumina; the soda of the sodium carbonate volatilizes; and embedded in the remaining crystals of graphite, etc., there are yellow crystalline particles, and a yellow crystalline crust of the nitride. F. Fichter strongly heated a mixture of aluminium bronze and charcoal in a covered crucible, and removed the lid when the mass was red-hot. A mixture of the oxide, carbide, and nitride was formed. L. Frank obtained the impure nitride by heating a mixture of aluminium powder and lime or calcium carbide in air. K. Kaiser prepared the nitride by the action of nitrogen on the heated sulphide. According to A. C. Vournasos, an impalpable powder of aluminium forms the nitride when heated with many organic nitrogenous compounds; thus, with thiocarbamide: $2Al+CS(NH_2)_2=2AlN+H_2S+H_2+C$; and with potassium or ammonium thiocyanate: $2KCNS+2Al=K_2S_2+2AlN+2C$, but there is a secondary reaction: $2K_2S_2+2AlN+2C=Al_2S_3+2KCN+K_2S$. Washing with alcohol gives a residue of carbon and aluminium. He also found that aluminium at 750° decomposes cyanogen and hydrogen cyanide, forming the nitride; and the same product is obtained by adding powdered aluminium to fused potassium cyanide—*vide supra*, boron nitride.

Aluminium nitride is manufactured commercially in O. Serpek's method of nitrogen fixation. Here, finely divided alumina or bauxite is mixed with carbon and heated in an atmosphere of nitrogen whereby aluminium nitride is formed: $Al_2O_3+3C+N_2=2AlN+3CO$. Bauxite reacts at 1550°, and alumina at rather a higher temp. owing to the favourable effect of the impurities—iron, silicon, nickel, manganese, and titanium oxides. The two first-named are the most active. O. Serpek said that the reaction is facilitated by gases with a small proportion of hydrogen chloride or sulphur dioxide, but S. A. Tucker and H. L. Read found sulphur dioxide to be harmful. The Badische Anilin- und Soda-Fabrik studied the effect of catalysts. The formation of the nitride from alumina and coal is greatly accelerated by the presence of 5–10 per cent. of oxides which can themselves form stable nitrides—*e.g.* those of silicon, titanium, zirconium, molybdenum, vanadium, beryllium, cerium, uranium, and chromium—as well as silicates, titanates, vanadates, etc. Silica is preferred on account of its cheapness. The presence of iron oxide and the other impurities in bauxite does not affect the catalytic agent, so that low-grade bauxite can be employed.

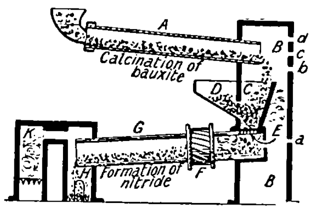

FIG. 14.—Diagrammatic Representation of O. Serpek's Aluminium Nitride Process.

The plant employed by O. Serpek consists of two superposed rotating cylindrical kilns, *A*, *G*, Fig. 14, slightly inclined towards one another and rotating in opposite directions. In the upper one, *A*, the powdered bauxite is introduced, and in its descent it is calcined and heated to about 1400° by the hot ascending gases. The calcined mass falls into the hopper, *C*, in the chamber, *B*, when it is mixed with the proper amount of coal from the hopper, *D*. The mixture enters the nitriding kiln, *G*, *viâ* openings, *E*, and then passes through a zone heated to 1800°–1900° by the detachable electric furnace, *F*, and lined with briquettes of aluminium nitride. The nitride collects in the chamber *H*. Producer gas passes from the producer *K*, enters the nitriding kiln flowing contrawise to the charge, is enriched by the carbon monoxide generated by the nitriding reaction. It leaves the kiln *G* and rising into the chamber *B* meets a current of air from *a*, *b*, *c*, *d*, it then enters the chamber *A*, and burns to carbon dioxide. O. Serpek stated that a mixture of hydrogen and nitrogen gives better results than producer gas in the rotary furnace. He also abandoned the rotary furnace in favour of a short chamber. The carbon-bauxite mixture was dropped through the nitrogen at 1250°–1300°, and the conversion is said to take place more rapidly than the 5–6 hrs. required in the rotary kiln. The aluminium nitride is then decomposed by water or alkali-lye, preferably, when ammonia is formed: $AlN+3H_2O=NH_3+Al(OH)_3$. If alkali-lye be used, the nitrogen is thus recovered as ammonia, and the alumina, virtually free from silica and iron, can be used for the production of alumina. The Badische Anilin- und Soda-Fabrik studied the best methods of treating the nitride with acid or alkali so as to recover the ammonia. The presence of soluble salts, like sodium chloride, favour the elimination by alkali-lye. W. Borchers and E. Beck tried a process involving electrolysis as indicated in connection with the alkaline earth nitrides—*vide supra.* O. Serpek's process has been discussed by T. H. Norton, E. Donath and A. Indra, J. W. Richards, O. Nissen, E. B. Maxted, C. Matignon, F. Marre, G. L. Bourgerel, W. von Escher, E. Bronnert, M. Shoeld, G. Herman, etc.

O. Serpek first used aluminium carbide as the raw material; and N. Caro showed that the absorption of nitrogen was then probably preceded by the dissociation of the carbide into carbon and aluminium. Better results were obtained commercially by heating a mixture of alumina and carbon in a current of nitrogen or producer gas; and O. Serpek here assumed that aluminium carbide is first formed, but there is no need for this assumption. S. A. Tucker and H. L. Read found that very little change takes place when the mixture of alumina and carbon is heated in nitrogen at 1600°; the reaction proceeds well at 1800°–2000°; but above 2000°, there are signs of a decomposition of the nitride. W. Fränkel showed that the velocity of absorption of dry nitrogen by a 2 : 1 mixture of alumina and carbon, is very small at 1350°; it increases to a moderate speed at 1500°, and above that temp. the absorption is rapid. Thus, in 30 mins.:

	1350°	1400°	1450°	1500°	1550°	1600°
Nitrogen absorbed .	0·2	3·1	4·4	8	19·5	24·5 per cent.

S. Peacock and E. I. du Pont found that a 3 : 1 mixture reacts with nitrogen at 1500° below 500 mm. press., forming *aluminium carbonitride*, $Al_2C_3N_6$, thus: $Al_2O_3+6C+3N_2=Al_2C_3N_6+3CO$; but W. Fränkel observed no indications of the formation of such a compound, at press. down to 250 mm. By working in atm. with variable proportions of nitrogen and carbon monoxide, he was able to show that the reaction: $Al_2O_3+3C+N_2\rightleftharpoons 2AlN+3CO$, is reversible. At one atm. press., and 1500°, the equilibrium conc. of carbon monoxide is between 25 and 40 per cent.; and at 1600°, between 50 and 65 per cent. At 1700°, nitrogen was still absorbed from an atm. with 70 per cent. carbon monoxide. Hence, by working with producer gas, a higher temp. is required than when working with an atm. of nitrogen. W. Hoopes, and N. F. O. Palacin made an impure nitride from the nitrogen in flue-gases. According to H. J. Krase and co-workers, if a ferro-aluminium containing 50 per cent. aluminium is heated at 1400° in nitrogen under atm. press., about 60 per cent. of the aluminium is converted into nitride. The presence of small amounts of magnesium promotes nitrification, whilst calcium, silicon, and titanium have the opposite effect. If small quantities of cryolite, or of the chlorides or fluorides of aluminium, magnesium, sodium, or calcium are present, nitrification may be rapid and practically complete even at 1200°. With ferrotitanium or aluminium carbide at 1400° the absorption of nitrogen is only about 20 per cent. of the theoretical, and with ferrosilicon, 2 per cent. C. Matignon found carborundum crystals in aluminium nitride made by passing nitrogen over a heated mixture of alumina and coke—the silicon was derived from the silica in the coke.

Aluminium nitride has been reported as a pale yellow, medium yellow, and and bluish- or greyish-black powder; and that prepared by J. W. Mallet was said to have some short rhombic prisms with the end faces making an angle of 120°. H. Ott found that the X-radiogram gave no evidence of a polar structure of the crystals. The crystals are hexagonal, with $a=3{\cdot}113$ A., and $c=1{\cdot}601$. The aluminium and nitrogen atoms are separately distributed in close, spherically packed, hexagonal lattices which are slightly compressed in the direction of the six-fold axis of symmetry, and displaced in the same direction. The basal group comprises two molecules, and each atom of either kind is surrounded tetrahedrally by four atoms of the other kind arranged at a uniform distance of 1·894 A. W. Hume-Rothery, and H. G. Grimm and A. Sommerfeld discussed the electronic structure. H. Herzer gave 3·045 to 3·053 for the sp. gr. at 25°/4°; 13·4 for the mol. vol.; and >1400° for the temp. of decomposition. C. Matignon said that aluminium nitride does not melt at 2200°, and at higher temp., it dissociates into its elements. K. F. Niessen studied the ionic charges in the crystals of the nitride. E. Friederich and L. Sittig gave 2200° for the m.p. under 4 atm. press. H. Hardtung gave 1100° for the temp. of formation and 1400° for the temp. of decomposition of aluminium nitride. The formation of the nitride is a strongly endothermal reaction. J. W. Richards gave —213·22 Cals., and W. Fränkel, —243 Cals. F. Fichter and E. Jenny gave (Al,N)=61·0 Cals.; and $2AlN+3O=Al_2O_3+N_2+258{\cdot}2$ Cals.; and for the heat of oxidation: $2AlN+3O=Al_2O_3+N_2+258{\cdot}2$ Cals. R. W. Riding and E. C. C. Baly studied the action of the cathode rays on the nitride. I. I. Shukoff found that the electrical resistance of the powdered aluminium nitride exceeds 2×10^6 ohms. H. Hardtung, and F. Fichter and A. Spengel said that *hydrogen* is without action on the nitride; but, according to F. Fichter, it decomposes when heated to redness in *oxygen*, forming alumina and nitrogen; and, according to J. W. Mallet, when heated in *air*, it becomes grey owing to the separation of alumina, but even after two hours' roasting in air, it still contained nitrogen. In moist air, the nitride gradually becomes sulphur-yellow and it crumbles to powder, forming aluminium hydroxide and ammonia. It is decomposed by *water* giving off ammonia: $AlN+3H_2O=NH_3+Al(OH)_3$. The Badische Anilin- und Soda-Fabrik worked out methods for treating the crude nitride to recover the ammonia, and obtain aluminium hydroxide of a high degree of purity. Thus, the crude nitride containing say silicon nitride can be treated with limited amounts of acid or alkali so as to obtain the alumina in a soluble form free from silica. It is also possible to arrange the proportion of acid or base so that the aluminium hydroxide remains insoluble: $2AlN+H_2SO_4+6H_2O=2Al(OH)_3+(NH_4)_2SO_4$. F. Fichter and A. Spengel said that dry *halogens* act slowly on the nitride—*chlorine* decomposes it at 760°, thus: $2AlN+3Cl_2=2AlCl_3+N_2$; while dry *hydrogen chloride* at a red-heat merely volatilizes some of the impurities in the nitride; but C. Montemartini and L. Losana found the nitrogen can be thus converted to ammonia and aluminium chloride is formed. The nitrogen is partly displaced when the nitride is heated with *sulphur*, and with *carbon disulphide* vapour. The nitride is rapidly decomposed by *sulphur chloride* vapour; and by heating with a mixture of 10 c.c. of conc. *sulphuric acid* and 40 c.c. of water. When heated with *phosphorus*, the nitrogen is partially displaced, but *phosphorus trichloride* is without action. There is no reaction with *carbon* at 1200°, and *carbon dioxide* acts as an oxidizing agent. H. Hardtung observed no formation of cyanide with *carbon monoxide* or carbon dioxide. F. Fichter and A. Spengel found that when aluminium nitride is fused with a mixture of *alkali carbonates*, and carbon, a large part of the nitride is converted into cyanide. Aluminium nitride and *alcohol*, at 230°, form triethylamine. Fused *potassium hydroxide* decomposes the nitride: $AlN+3KOH=K_3AlO_3+NH_3$; and the reaction with *sodium dioxide* is incomplete —some nitrate is formed. Fused *lead dichromate* decomposes the nitride completely. N. Tschischewsky found that aluminium nitride dissolves in iron, and if aluminium is present in iron, it can retain and hold nitrogen as aluminium nitride.

F. Fischer and co-workers [12] reported **indium nitride**, InN, and **thallium nitride**, TlN, to be formed by the process outlined in connection with Fig. 11. According to E. C. Franklin, the interaction of liquid ammonia soln. of thallium nitrate and potassamide according to the equation: $3TlNO_3+3KNH_2=Tl_3N+3KNO_3+2NH_3$, yields a dense black precipitate of the **thallous nitride**, Tl_3N, which is readily soluble in excess of potassamide and also in liquid ammonia soln. of ammonium nitrate. In the latter case, the thallium nitride is reconverted into nitrate, thus: $Tl_3N+3NH_4NO_3=3TlNO_3+4NH_3$. E. Friederich and L. Sittig obtained **scandium nitride**, ScN, by heating a mixture of the oxide and carbon in nitrogen gas. E. Friederich gave *c.* 2920° for the m.p. and said that no perceptible volatilization occurs at the m.p. He gave 3·08 ohms for the sp. electrical resistance. K. Becker and F. Ebert found that scandium nitride has cubic crystals with an X-radiogram corresponding with a density 4·21, and an elementary cube of side 4·44 A. L. Pauling discussed the lattice-structure. E. Friederich and L. Sittig gave 4·2 for the sp. gr., and 2650° for the m.p. There is no perceptible volatilization at the m.p. C. Matignon prepared **lanthanum nitride,** LaN; **praseodymium nitride,** PrN; **neodymium nitride,** NdN; and **samarium nitride,** SaN, by heating a mixture of the oxide with powdered magnesium or aluminium in an atm. of nitrogen; or heating the chloride with sodium in an atm. of nitrogen. W. Muthmann and K. Kraft found that lanthanum does not burn in nitrogen, but the metal absorbs the gas at a red-heat, 850°–900°. When lanthanum is burnt in dry air, more than half is converted into nitride; the union of lanthanum with nitrogen commences at a lower temp. than is the case with oxygen (440°–460°). It is also formed when lanthanum is heated in dry ammonia. A. C. Vournasos made lanthanum nitride by heating the metal in cyanogen or hydrogen cyanide at 750°, or by adding the finely divided metal to fused potassium cyanide as in the case of boron nitride—*vide supra.* Lanthanum nitride is stated by W. Muthmann and K. Kraft to be a dull black solid which slowly decomposes in moist air with the evolution of ammonia. It reacts with water less violently than cerium nitride: $LaN+3H_2O=La(OH)_3+NH_3$; and with acids it forms salts of lanthanum and ammonium. G. Tammann measured the rates of formation of lanthanum nitride. E. Friederich and L. Sittig obtained impure **ytterbium nitride,** and lanthanum nitride, by heating a mixture of the oxide and carbon in nitrogen. E. Friederich and L. Sittig made **erbium nitride,** ErN, by the action of nitrogen on a heated mixture of erbia and carbon.

The **carbon nitrides** are represented by cyanogen as a type; and these compounds are discussed elsewhere. Three **silicon nitrides** have been reported, *viz.* SiN, Si_3N_4, and Si_2N_3. H. St. C. Deville and F. Wöhler[13] employed an ingenious method for preparing silicon nitride. Crystalline silicon was placed in a crucible which was placed in a larger crucible with carbon packing in the annular space between the two crucibles. The combination was heated white-hot. The penetration of oxygen from the air to the inner crucible was prevented, while atm. nitrogen could pass the carbon into the inner crucible. The preparation of nitrogen as a separate process is not therefore necessary. G. Tammann said that no reaction occurs between nitrogen and silicon at 700°. The union of the two elements furnishes **silicon hemitrinitride,** Si_2N_3. P. Schützenberger and co-workers obtained the same white product; they removed the free silicon by washing with potashlye.

According to P. Schützenberger and A. Colson, *carbazot-silicium,* or *silicon dicarbonitride,* Si_2C_2N, is formed when crystallized silicon is heated to whiteness in a brasqued crucible. The product, after washing with boiling potash to remove silicon, and treatment with hydrofluoric acid to remove silica and silicon nitride, is a bluish-green, pulverulent mass. Silicon dicarbonitride is insoluble in alkalies and in all acids. Heated to redness in oxygen or with cupric oxide, it undergoes no sensible change, but when heated with litharge, lead dioxide, or a mixture of litharge and lead chromate, it burns brilliantly, with formation of oxides of nitrogen and carbon dioxide. L. Weiss and T. Engelhardt found that heating silicon in the flame of a coke fire gives a product approximating *silicon tricarbonitride,* Si_3C_3N. A. Colson obtained *silicon cyanide,* SiCy, by the action of mercuric cyanide on silicon disulphide in dry benzene.

According to L. Wöhler and O. Bock, when nitrogen is passed over calcium disilicide heated at 1150°, a grey mass containing about 22·5 per cent. of nitrogen is formed. This consists principally of **calcium silicocyanamide, or calcium silicodinitride,** $CaSiN_2$, **calcium silicocyanide, or calcium disilicodinitride,** $Ca(SiN)_2$, and silicon, $2CaSi_2+2N_2=CaSiN_2+Si+Ca(SiN)_2$, together with small quantities of calcium nitride, Ca_3N_2, and silicon nitride, Si_3N_4. Under similar conditions, calcium monosilicide yields first an intermediate product, **calcium siliconitride,** CaSiN, or $Ca_2Si_2N_2$, $Ca_2Si_2+N_2=Ca_2Si_2N_2$; and then calcium silicocyanamide, $Ca_2Si_2N_2+N_2=2CaSiN_2$, but a considerable portion of the monosilicide is transformed into disilicide and calcium during the heating. Neither calcium silicocyanamide nor calcium siliconitride could be isolated from the reaction products, but both substances dissolved in hydrochloric acid without separation of silica. The rate of absorption of nitrogen by calcium disilicide is greatly accelerated by addition of calcium chloride or of less than 5 per cent. of calcium fluoride to the reaction mixture and takes place at temp. as low as 850° in the presence of these catalysts. In the presence of 50 per cent. of calcium chloride, a mixture of lime and ferro-silicon containing 90 per cent. Si absorbs 20·7 per cent. of nitrogen at 1050°–1100°, forming calcium silicocyanamide and calcium metasilicate. Barium oxide and magnesia under similar conditions give analogous products. Calcium silicocyanide is insoluble in hydrochloric acid, but soluble in a mixture of hydrofluoric and sulphuric acids, to which it yields its nitrogen as ammonium salt.

A. Geuther said that the reaction between silicon and nitrogen occurs only slowly below the m.p. of silicon; and at a bright red-heat, calcium or magnesium silicide in an atm. of nitrogen furnishes only the nitride of the more basic element, the silicon separates in its elemental state. E. Vigouroux observed no reaction between amorphous silicon and nitrogen at 1000°, but at a higher temp., a nitride was formed. H. Mehner obtained the nitride from a heated mixture of silica and carbon in an atm. of nitrogen. According to L. Weiss and T. Engelhardt, when silicon is heated in a porcelain boat in an atm. of nitrogen, combination begins above 1250°, since they found that after half an hour's heating at different temp., the nitrogen absorbed per gram of silicon was :

	1295°	1300°	1310°	1320°	1400°	1480°
Nitrogen . .	0·0001	0·0001	0·0002	0·0014	0·0049	0·0061 gram

N. Tschischewsky made the nitride by working at 1400°. About 4 per cent. of the silicon volatilizes during the reaction. The product obtained after heating the silicon in nitrogen for an hour is an amorphous, voluminous, white powder which, under the microscope, seems to consist of several different substances. The composition of the final product is dependent on the mode of purification; if boiled with potassium hydroxide soln., followed by treatment with hydrofluoric acid, a product containing silicon hemitrinitride mixed with silica is obtained. The silica could not be removed from the nitride. M. Blix and W. Wirbelauer obtained the nitride by heating silicam, Si_2N_3H, between 1200° and 1400°; and H. St. C. Deville and F. Wöhler, by the action of ammonia on silicon chloride.

According to P. Schützenberger, when silicon tetrachloride is sat. with dry ammonia, a white compound, *silicon decanitridohydrotrichloride*, $Si_8N_{10}Cl_3H$, is formed, and this is decomposed by water with the separation of silica; when heated in a current of ammonia, *silicam*, Si_2N_3H, is formed. Later, P. Schützenberger said that dry ammonia converts silicon tetrachloride into *silicon hexanitridodichloride*, $Si_5N_6Cl_2$, thus: $5SiCl_4+24NH_3=18NH_4Cl+Si_5N_6Cl_2$; and this when heated with ammonia forms silicam, $2Si_5N_6Cl_2+7NH_3=4NH_4Cl+5Si_2N_3H$. This subject was discussed by J. Persoz, and J. A. Besson.

According to H. St. C. Deville and F. Wöhler, and P. Schützenberger, silicon hemitrinitride is a white, amorphous substance which does not melt in ordinary furnaces. W. Jevons attributed the bands in the spectrum of silicon tetrachloride with a little air to the formation of a silicon nitride. R. S. Mulliken, E. Woldering, and W. Jevons studied the band spectrum of silicon nitride. According to H. St. C. Deville and F. Wöhler, and P. Schützenberger, silicon heminitride is not altered when heated in air; but in moist air it slowly decomposes, and smells of ammonia. The same remark applies to the action of water at ordinary temp. It is decomposed by steam, with the formation of amorphous silica. The nitride is decomposed by hydrofluoric acid, forming ammonium fluosilicate, and, according to P. Schützenberger, liberating ammonia. Dry chlorine has no action at a bright red-heat; and aq. acids and alkalies have no action on the nitride. Molten potassium hydroxide dissolves it with the liberation of ammonia, and the formation of potassium silicate; molten potassium hydroxide forms potassium cyanate, and if the nitride is in excess, potassium cyanide. When heated with red-lead, nitrogen trioxide is formed with incandescence, and when fused with lead dichromate, nitrogen gas is given off. L. Weiss and T. Engelhardt gave 3·22 for the sp. gr. of the product with 19·84 per cent. SiO_2, and 3·64 for the pure nitride. Its properties resemble those of the normal nitride.

L. Weiss and T. Engelhardt found that if the product of the action of nitrogen on silicon at 1300°–1400° be treated with a mixture of nitric and hydrofluoric acids, the hemitrinitride is probably broken down, because the residue has the composition of **silicon mononitride,** or **silicocyanogen,** SiN, plus about 13·55 per cent. SiO_2. The sp. gr. of the impure nitride is 2·99, and of the pure nitride, 3·17. It loses 36·6–44·8 per cent. of its nitrogen content by heating 3–6 hrs. with conc. sulphuric acid. Its properties resemble those of the normal nitride. P. Schützenberger claimed to have prepared this nitride in 1879.

L. Weiss and T. Engelhardt showed that if silicon be heated between 1300° and 1400° in an atm. of nitrogen, the progress of the absorption from hour to hour is as follows:

Time . . .	1st	2nd	3rd	4th	5th	6th	7th
Increase in weight	22·47	11·68	10·87	4·74	1·81	0·92	0·05 per cent.

so that the total amount of nitrogen absorbed was 58·54 per cent. This corresponds very nearly with that required for *normal silicon nitride*, or **silicon tritatetranitride,** Si_3N_4. P. Schützenberger claimed to have prepared this nitride in 1879. E. Friederich and L. Sittig made it by the action of silica, carbon, and nitrogen at 1250°–1300°. According to H. Funk, the finely divided silicon obtained by cooling a 10 per cent. soln. of that element in aluminium forms this nitride after 10 mins.' heating in nitrogen at 1450°, whereas crystalline silicon requires several hours. L. Weiss and T. Engelhardt found that this compound is a greyish-white amorphous powder, whose sp. gr. when contaminated with 9·67 per cent. of silica was 3·26, thus leaving 3·44 for the pure nitride. E. Friederich and L. Sittig gave 3·44 for the sp. gr., and said that the crystals are not cubic. They gave 1900° for the m.p. under press., and found that the nitride sublimes before melting. The electrical resistance is very large. Silicon nitride is very inert chemically. Water vapour at 100° has very little action, the merest trace of ammonia can be detected; a similar result was obtained with superheated steam at 800°. Dil. acids, excepting hydrofluoric acid, have no action; but heating with conc. sulphuric acid results in the slow production of ammonium sulphate—after 3–6 hrs.' heating, 42·1–45·8 per cent. of the contained nitrogen was given off. Hydrofluoric acid decomposes the nitride, especially after a preliminary treatment with potassium hydroxide, forming ammonium fluosilicate; but it is fairly stable in contact with a mixture of nitric and hydrofluoric acids. Ammonia is evolved when the nitride is fused with potassium hydroxide; and when heated with potash-lye, nitrogen is given off. Lead chromate, lead dioxide, and lead monoxide are reduced with the evolution of nitrogen. N. Tschischewsky found molten iron dissolves about 0·75 per cent. of silicon nitride.

The Badische Anilin- und Soda-Fabrik prepared a nitride of undetermined composition by heating a mixture of silica and carbon in an atm. of nitrogen. The reaction proceeds at a relatively low temp. if a hydroxide or salt of a metal be added. The product contains silicon nitride mixed with the nitride of the metal. The Badische Anilin- und Soda-Fabrik also removed many of the impurities—iron, carbon, silicates, carbides, silicides, and phosphides—by treatment with acids or mild oxidizing agents which do not affect the silicon nitride. A. S. Larsen and O. J. Storm prepared the nitride by the action of nitrogen on molten silicides—*e.g.* ferrosilicon.

In 1850, F. Wöhler[14] drew attention to the magnitude of the affinity of nitrogen for titanium, for the two elements readily unite together at a high temp., forming **titanium nitride**; and F. Wöhler and H. St. C. Deville said that it is difficult to prepare titanium by reduction because of the penetration of atm. nitrogen into the heated vessel and the consequent formation of the reddish-brown nitride. Four nitrides have been reported, *viz.*, TiN, Ti_5N_6, Ti_3N_4, and TiN_2. There is some doubt about the chemical individuality of the first, second, and last of these substances. F. Wöhler and H. St. C. Deville obtained the nitride by heating a mixture of sodium and potassium fluotitanate in a porcelain boat in a hard glass tube through which a current of nitrogen was passed. The salt was transformed into a bronze-coloured mass of the nitride. They also obtained titanium nitride by passing a mixture of hydrogen and nitrogen, carrying the vapour of titanium tetrachloride, over molten sodium, or aluminium; by passing nitrogen over a fused mixture of potassium fluotitanate, sodium chloroaluminate, and aluminium. H. Mehner heated a mixture of titanic oxide and carbon in an atm. of nitrogen. A. E. van Arkel and J. H. de Boer obtained the nitride by passing the vapour of the chloride mixed with nitrogen over a heated tungsten filament. G. Tammann noted a formation of a film of nitride when titanium is heated in nitrogen. F. von Bichowsky described the manufacture of this compound. The Titan Co., and F. von Bichowsky and J. Harthan obtained impure titanium nitrides for the production of ammonia by treatment with acids.

C. Friedel and J. Guérin claimed to have prepared **titanium mononitride,** or **titanocyanogen,** TiN, or Ti_2N_2, by the action of dry ammonia on titanic oxide, or titanium sesquioxide at a red-heat; by heating titanium tritatetranitride at a dull red-heat in a stream of dry hydrogen or ammonia; and by the action of cyanogen on a mixture of titanic oxide and carbon at a bright red-heat. H. Moissan obtained it by melting titanic oxide—with or without carbon—titanium, or titanium carbide in a high temp. electric furnace. E. Friederich and L. Sittig made it by the action of carbon or hydrogen on titanic oxide at 1300° followed by treatment with nitrogen. L. Weiss and H. Kaiser obtained it by heating titanium in a stream of nitrogen in a porcelain tube at 1400°; and O. Ruff and F. Eisner, by heating the tetratritanitride in a stream of ammonia at 1500°. H. Hardtung obtained the nitride by heating titanium in ammonia for 6 hrs. at 900°–1000°. G. G. Henderson and J. C. Galletly prepared a nitride by the action of ammonia on heated titanium. The Badische Anilin- und Soda-Fabrik has discussed the purification of the nitride by the process indicated in connection with silicon nitride. H. Moissan described it as a hard, tough, fusible, bronze-coloured mass which has a sp. gr. of 5·18, and is hard enough to scratch the ruby, but can be scratched by the diamond; O. Ruff and F. Eisner gave 5·10 for the sp. gr. at 18°; and C. Friedel and J. Guérin say that it is an amorphous, brass-yellow powder which has a sp. gr. of 5·28 at 18°, and is hard enough to scratch the topaz. H. Herzer gave 5·122 for the sp. gr. at 25°/4°; and 12·1 for the mol. vol. E. Friederich and L. Sittig gave 5·18 for the sp. gr.; 2927° for the m.p.; and found the space-lattice to correspond with a face-centred cube of the sodium chloride type with edge 4·40 A.; A. E. van Arkel gave 4·23 A. There are 4 mols. in each elementary cell. The compound melts at 2930° and does not sublime before melting. It is a good conductor of electricity, the sp. resistance being $1·3\times10^{-4}$ ohm at room temp., and $3·4\times10^{-4}$ ohm at the m.p. I. I. Shukoff observed that the electrical conductivity of powdered titanium nitride, 31·05 mhos, is of the same order as that of the metals, and he therefore argued that the titanium nitrides are not chemical compounds but solid soln. of nitrogen in titanium. C. Friedel and J. Guérin showed that when heated in air, it oxidizes to titanic oxide; with molten potassium hydroxide, it furnishes ammonia; it is dissolved by sulphuric acid with the evolution of sulphur dioxide; and when heated with copper oxide to redness, the nitrogen is all driven off. E. Friederich and L. Sittig found the bronze-yellow nitride is insoluble in boiling sulphuric, nitric, or hydrochloric acid, but it is quickly dissolved by hot *aqua regia;* boiling potash-lye or soda-lye furnishes ammonia. O. Ruff and F. Eisner said that neither chlorine gas at 270°, nor liquid chlorine is able to convert it into chloronitride; and C. Montemartini and L. Losana showed that when the nitride is heated in a current of hydrogen chloride, titanium chloride and ammonia are formed; and they studied the partition of dry or moist oxygen and nitrogen between titanium.

F. Wöhler said that *titanium pentitahexanitride,* Ti_5N_6, is formed when the tetratritanitride is heated in a current of hydrogen until, below redness, the evolution of ammonia begins. It is said to remain undecomposed when heated in air at about 1083°. C. Friedel and J. Guérin said that this compound is an impure form of the mononitride. F. Wöhler calcined titanic oxide in a stream of dry ammonia, cooled the product in the same gas, and obtained what he regarded as *titanium dinitride*, TiN_2. O. Ruff claimed to have made the dinitride by heating titanic oxide to at least 1000°—better at 1400°–1500°—in a current of dry ammonia. H. Geisoff did not obtain it by the action of ammonia on liquid titanium tetrafluoride. F. Wöhler and H. St. C. Deville did not obtain it by strongly heating titanic oxide in a current of mixed hydrogen and nitrogen gases. The dinitride was said to be a dark violet powder with a coppery appearance like sublimed indigo. Its properties resemble those of the hexapentitanitride. C. Friedel and J. Guérin, and P. Hermann regarded the dinitride as an impure form of the mononitride ; and O. Ruff and F. Eisner say that the nitrides Ti_2N, TiN_2, and Ti_3N_4 are impure forms of TiN.

H. Rose's first report of the isolation of titanium shows that he had mistaken what F. Wöhler called *Stickstofftitan* for elemental titanium. This substance is really **titanium tritatetranitride,** Ti_4N_3. It is also probable that the titanium reported by C. Despretz to be formed from titanium tetrachloride as a brown powder was really this nitride. H. Rose, J. Persoz, and J. von Liebig obtained it by the action of heat on titanium amminochloride ; F. Wöhler, by passing the vapours of ammonium and titanium chlorides through a red-hot tube. H. Geisoff used a mixture of the vapour of ammonia and titanium tetrachloride. E. A. Schneider found that F. Wöhler's nitride always contained up to 5·4 per cent. of oxygen. C. Friedel and J. Guérin recommended driving the air out of the apparatus with a stream of hydrogen chloride. O. Ruff and F. Eisner, and N. Whitehouse obtained this nitride by heating titanium amminochloride in a stream of ammonia. J. von Liebig described this nitride as forming a dark violet-blue powder, or coppery-looking mass resembling sublimed indigo. W. Hermann said that the violet colour produced by titanium in the blowpipe bead with fused microcosmic salt is really titanium nitride ; and suggested that titanium nitride may be the pigment in the amethyst. C. Friedel and J. Guérin said that it forms what are probably rhombohedral crystals. K. Becker and F. Ebert found the X-radiogram of the cubic crystals corresponded with a sp. gr. 4·81, and an elementary cube of side 4·40 A. H. Rose said that a thin film on glass is red in reflected and green in transmitted light. F. Versmann said that a bright yellow colour is formed when this nitride is heated in *hydrogen ;* but H. Hardtung obtained only one per cent. of ammonia during an hour's action of hydrogen on titanium nitride at 1000°. In 1872, C. M. Tessié du Motay suggested obtaining nitrogen from the atmosphere by first making the tritatetranitride, and then splitting off nitrogen and ammonia by heating the product in a current of hydrogen so as to produce the mononitride. The mononitride can be transformed into the tritatetranitride by heating it in a current of nitrogen, and thus the cycle begins anew. According to F. Wöhler, when heated in *air,* it oxidizes to titanic oxide in a crystalline form. When the oxidation is nearly ended, the product emits a noise possibly due to an allotropic change in the titanic oxide. The nitride forms titanium tetrachloride when heated in *chlorine,* and if an intimate mixture of nitride and *carbon* is heated in chlorine, it does not form $TiCl_4.CyCl$. C. Montemartini and L. Losana observed that when heated in *hydrogen chloride,* the nitrogen is quantitatively converted into ammonia. H. Hardtung observed no formation of cyanides during the action of *carbon monoxide* or of *carbon dioxide* on titanium nitride. The Badische Anilin- und Soda-Fabrik reported that if this nitride be mixed with carbon and the oxides, or salts of the alkali or alkaline earth metals, and fused, cyanides or cyanamides are produced. O. Ruff and F. Eisner said that the nitride is insoluble in dil. *acids ;* it is decomposed by hot conc. *sulphuric acid,* and conc. *nitric acid,* especially if *hydrofluoric acid* be also present. H. Rose found the nitride dissolves with difficulty in hot nitric acid, but readily in *aqua regia.* M. Wunder and B. Jeanneret found that titanium nitride is opened up by heating it with *phosphoric acid* of sp. gr. 1·75. O. Ruff and F. Eisner said that the nitride is decomposed by a boiling soln. of *potassium hydroxide.* I. I. Shukoff considers the so-called titanium nitride to be solid soln. H. B. Landmark patented a process for fixing the nitrogen of the atm. by means of titanium nitride and the subsequent conversion of the nitrogen into ammonia.

Like titanium, zirconium readily forms a nitride when heated in an atm. of nitrogen. This was demonstrated by J. W. Mallet,[15] who worked with zirconium contaminated with aluminium; by E. Wedekind, who worked with a metal contaminated with magnesium; and by C. Matignon. E. Wedekind also obtained the nitride by heating the carbide to redness in an atm. of nitrogen. J. W. Mallet heated amorphous zirconium in a lime crucible at about 1750°. Amorphous zirconium in an atm. of ammonia at a dull red-heat forms the nitride with incandescence. E. Wedekind, and F. P. Venable and R. O. Dietz found that when zirconium chloride is heated in ammonia, or amorphous zirconium in cyanogen gas, the nitride is formed. Two nitrides have been reported, Zr_2N_3, and Zr_3N_8. The former is the more clearly defined. Powdered zirconium, dried, and freed from gases, combines directly with but relatively small amounts of nitrogen when heated in that gas below 1000°; thus, at 800°, the metal took up 1·6 per cent. of gas, but when heated to 1050°, the metal acquired a yellow or olive-green colour, and finally became grey. The product contained 9·24 per cent. of nitrogen corresponding with zirconium : nitrogen=3 : 2. A. E. van Arkel and J. H. de Boer made zirconium nitride by the process they used for the titanium nitride. So also with **hafnium nitride**. F. Wöhler, and J. M. Matthews obtained **zirconium tritaoctonitride**, Zr_3N_8, by gradually raising the temp. of zirconium octamminotetrachloride in an atm. of nitrogen. The grey powder burns in air to form zirconia. P. Bruère and E. Chauvenet could not prepare either Zr_3N_8 or Zr_2N_3. By heating zirconium tetramminotetrachloride at 300°, they obtained **zirconium tritatetranitride**, Zr_3N_4, and not F. Wöhler's Zr_3N_8. E. Friederich and L. Sittig represent the pale yellowish-brown powder obtained by heating zirconium oxide and carbon in nitrogen as **zirconium nitride**, ZrN. The space-lattice is a regular face-centred cube of the sodium chloride type, with sides 4·63 A. There are four mols. per unit cell. The sp. gr. of the fused nitride is 6·93. A. E. van Arkel made observations on this subject. The m.p. is 2930°, and it does not sublime before melting. The electrical resistance is $1{\cdot}6\times10^{-4}$ ohm at ordinary temp. and $3{\cdot}2\times10^{-4}$ at the m.p. E. Wedekind obtained **zirconium hemitrinitride**, Zr_2N_3, by the reduction of zirconium by magnesium in an open crucible; and removed the zirconia by flotation in tribromomethane. J. M. Matthews also prepared it by heating zirconium tetrachloride to redness in dry ammonia. J. M. Matthews' product was an amorphous, dark grey powder; while under the microscope, E. Wedekind's product appeared as bronze-coloured crystals with a green shimmering lustre. The sp. gr. was 6·75 at 15°. K. Becker and F. Ebert found the X-radiogram corresponded with an elementary cube of side 4·63 A., and density 6·97; A. E. van Arkel gave 4·59 A. for the side of the cube. The compressed powder is an electrical conductor. There is no perceptible dissociation of the nitride at 1100°; and it is not affected by heating to redness in a current of hydrogen, but at 1050°, ammonia begins to be formed—in the converse reaction, nitrogen acts on the hydride also forming ammonia. When heated in air, it glows with the formation of zirconia. At a red-heat, the nitride reacts with chlorine or bromine with incandescence; it is more resistant to oxygen and chlorine than is the metal. It is very stable towards acids—excepting hydrofluoric acid which decomposes the nitride giving off ammonia gas. Aq. soln. of the alkali hydroxides do not act on the nitride; but with fused potassium hydroxide, ammonia is evolved.

C. Matignon[16] prepared **cerium nitride**, CeN, by reducing the oxide with magnesium or aluminium in an atm. of nitrogen; or the chloride with sodium in an atm. of nitrogen. A. C. Vournasos prepared it by adding the powdered metal to fused potassium cyanide as in the case of boron nitride; and J. Lipsky, by the action of ammonia on the hydride. W. Muthmann and K. Kraft found that cerium at a moderate red-heat acts but slowly on nitrogen, but at 850°, there is a sudden and violent reaction, the formation of the nitride being accompanied by a brilliant incandescence. If the nitrogen contains a small proportion of oxygen or nitrogen oxides, the product is dark grey, and contains an oxide; but with purified nitrogen, the nitride is bronze-coloured, almost black. G. Tammann measured the rate of formation of nitride when cerium is heated in nitrogen. On the other hand, F. W. Dafert and R. Miklauz said that the nitride cannot be obtained from its elements, but is formed by heating the hydride in nitrogen at 800°–900°. E. Friederich and L. Sittig obtained a trace of the nitride by heating a mixture of the oxide and carbon at 1250°. F. Fichter and C. Schölly observed that when cerium carbide is heated in nitrogen it does not behave like calcium nitride at 1250°, and form cyanide or cyanamide, but rather forms cerium nitride, CeN. Cerium carbide also reacts with ammonia at 1250°, yielding the nitride, but the action is slower and less complete than is the case with nitrogen. A. C. Vournasos said that the nitride is easily oxidized in air, and consequently he was not able to eliminate carbon by ignition in air. J. Lipsky found the dissociation press. to be immeasurably small at 320°; between 6 mm. and 13 mm. at 460°; 340 mm. at 610°; 370 mm. at 675°; 380 mm. at 715°; and 400 mm. at 762°. The data are only approximate because equilibrium is attained very slowly—due to the equilibrium being quickly established on the surface, the nitride then dissolving in the metal, and further change being then dependent on diffusion in the solid. The change was not accelerated by admixtures of alkali or alkaline earth chlorides. Purified and dried nitrogen when passed over the freshly prepared hydride in the cold, reacts quickly, forming ammonia; the reaction, $CeH_3+N_2 \rightleftharpoons CeN+NH_3$, quickly slows down owing to the formation of a protective superficial film of nitride. Raising the temp. 200° accelerates the reaction very little. No ammonia is formed by the action of hydrogen on cerium nitride in the cold, but between 100° and 400° —preferably 200°—ammonia is formed: $CeN+3H_2 \rightleftharpoons NH_3+CeH_3$. F. W. Dafert and R. Miklauz said that ammonia is not formed by the action of hydrogen on the heated nitride. J. Lipsky found that a mixture of hydrogen and nitrogen gases acting on cerium nitride at 25° furnishes ammonia. The catalytic reaction stops in about 24 hrs., possibly owing to the presence of moisture and oxygen in the mixed gases. The continuous production of ammonia soon stops if a mixture of nitrogen and hydrogen is used, but it goes on continuously (although slowly) when nitrogen and hydrogen are passed alternately at short intervals. A mixture of hydride and nitride gives the best results, and the rate of production is very much increased by spreading the material out over a large surface of asbestos, glass wool, or copper gauze. When the contact material is allowed to cool off and remain unused for some hours, its activity increases. The quantity of ammonia produced is proportional to the quantity of contact material used, and independent, within fairly wide limits, of the rate of passage of the gas. The highest conc. of ammonia reached was 6·4 per cent. by vol. in the gas passed over cerium nitride; and 1·4 per cent. over the hydride. N. Woodhouse, and J. Lipsky made some observations on the fixation of nitrogen as ammonia *viâ* cerium nitride as intermediary. W. Muthmann and K. Kraft said that the nitride suffers no change in dry air, but in contact with moisture, ammonia is evolved; the mass finally becomes hot and glows as it is oxidized to ceric oxide. The reaction with water is violent; and if a few drops of water be sprinkled on the nitride, the mass becomes bright red as it is converted into ceric oxide—ammonia and hydrogen are evolved and burn: $2CeN+4H_2O=2CeO_2+2NH_3+H_2$. The nitride dissolves quietly in an aq. soln. of potassium hydroxide, forming cerous hydroxide and ammonia. With dil. acids the dissolution is accompanied by the formation of cerous and ammonium salts: $2CeN+4H_2SO_4=Ce_2(SO_4)_3+(NH_4)_2SO_4$. The reaction with dil. acids is sometimes so violent that the mass becomes incandescent, and at the high temp., some ammonia is decomposed into its elements. According to P. Fabaron, when metallic cerium is heated in a closed copper tube, the oxygen of the air in the tube combines with the copper and the nitrogen with the cerium. The **cerium dinitride,** CeN_2, formed has a greyish-black colour and is decomposed by water, yielding ammonia and cerous oxide.

According to J. J. Chydenius,[17] thorium oxide is not changed when heated in ammonia; but if thorium tetrachloride alone or mixed with ammonium chloride is heated in ammonia gas, a white insoluble powder is formed which gives off ammonia when fused with potassium hydroxide. E. Chauvenet obtained what appeared to be thorium nitride by heating thorium tetramminotetrachloride at a red-heat. E. Friederich and L. Sittig obtained the impure nitride by heating a mixture of the oxide and carbon in a current of nitrogen. H. Moissan and A. Étard made **thorium nitride,** presumably Th_3N_4, by heating the carbide at 500° in an atm. of ammonia. A. E. van Arkel and J. H. de Boer made thorium nitride by the process they used for titanium nitride. C. Matignon made this compound by heating a mixture of thorium dioxide and magnesium in an atm. of nitrogen; and C. Matignon and M. Delépine, by heating thorium in nitrogen gas—since the absorption by thorium itself is slow, thorium hydride can be used. The dark brown nitride is not altered at a red-heat. It burns in air with incandescence; and in oxygen, the incandescence is very vivid, being probably due to thorium. Cold water decomposes the nitride slowly; hot water, rapidly, forming thorium hydroxide and ammonia. Dil. acids decompose the nitride, forming ammonium and thorium salts; and with alkali-lye, ammonia is formed.

V. Kohlschütter prepared what he called *thorium metanitride,* a polymer of the tetratritanitride, by heating a mixture of thoria and magnesium to a high temp. in the presence of nitrogen. The citron-yellow product is less reactive than the tetratrinitride just described. It is said to be insoluble in conc. and dil. acids, and with water, to form hydrogen. It is attacked when heated in oxygen, or chlorine; and when fused with alkali hydroxide. C. Matignon and M. Delépine consider it to be an oxynitride, $Th_4O_5N_2$.

K. Iwase[18] found out tin does not dissolve nitrogen. G. G. Henderson and J. C. Galletly heated tin in ammonia from 160° to redness, and found that the metal retained no marked amount of nitrogen; from 170°, the metal became matte, and showed rounded globules when viewed under the microscope. When the temp. approached redness, the ammonia was decomposed by the metal. It was assumed that an unstable nitride was formed. F. Fischer and co-workers prepared an impure **tin nitride,** by the method indicated in connection with Fig. 11. When treated with cold hydrochloric, sulphuric, phosphoric, or oxalic acid, the nitride is not changed, but with hot hydrochloric, sulphuric, or phosphoric acid, the mass is dissolved. There is only a slight reaction with cold conc. nitric acid; boiling conc. nitric acid attacks it only slowly; the dil. acid, cold and hot, attacks the preparations more. G. G. Henderson and J. C. Galletly found the action of nitrogen on lead resembled its action on tin. P. Herrmann found that ammonia reduces lead chloride at 500°–600° to lead; and at 0°–250°, spongy lead absorbs no nitrogen. F. Fischer and F. Schröter reported an impure **lead nitride** to be formed by the method given in connection with Fig. 11. The product was said to be very unstable, and explosive; and to yield an ammonium salt with acids. W. Beltz discussed the stabilization of lead nitride.

According to H. B. Baker and H. B. Dixon,[19] red phosphorus heated to 300° in a stream of nitrogen suffers no change. A. Stock and H. Grüneberg also obtained no phosphorus nitride by the action of nitrogen or ammonia gas on phosphorus. If a very high temp. were employed, there might be a reaction. W. P. Winter reported that when sodamide is warmed with yellow phosphorus, an energetic reaction occurs, and the product is a mixture of sodium phosphide, oxy-acids of phosphorus, and probably a phosphorus amide. According to H. Schiff, the phosphorus nitride reported by H. Rose, and F. Wöhler and J. von Liebig, is probably phospham, PN_2H. W. H. Balmain reported a phosphorus nitride, of undetermined composition, to be formed by the action of phosphorus on hot mercuric chloroamide. W. Moldenhauer and H. Dörsam found that when yellow phosphorus is distributed as evenly as possible over the inside of a glass tube, it readily absorbs nitrogen at 180–200 mm. press. when exposed to electric discharges between aluminium electrodes. The product is a mixture of unchanged white phosphorus, red phosphorus, and **phosphorus mononitride,** PN. It is extracted with carbon disulphide, and the residue is heated in a porcelain boat in a slow current of nitrogen at 500°–550° and 12 mm. press.; the nitride thus acquires some impurities from the porcelain. It is a voluminous, yellowish-brown powder, extraordinarily resistant to chemical agents.

According to A. Besson, when phosphamide is heated in a current of nitrogen in a porcelain tube at a high temp., the end-product of the reaction corresponds with *phosphorus mononitride*, PN. A. Stock and H. Grüneberg, however, were unable to find any nitride other than P_3N_5.

F. Briegleb and A. Geuther prepared *phosphorus tritapentanitride*, or **phosphorus nitride,** P_3N_5, by passing the vapour of phosphorus pentachloride accompanied by nitrogen over heated magnesium nitride: $5Mg_3N_2+6PCl_5=15MgCl_2+2P_3N_5$; and E. A. Schneider's nitride obtained by using phosphorus trichloride is probably the same compound. A. Stock and B. Hoffmann obtained this same nitride by heating the products of the action of dry ammonia on phosphorus pentasulphide at 230°; and by heating ammonium iminotrithiophosphate, $(NH_4S)_3PNH$, in a current of ammonia. A. Stock made it by heating iminotrithiophosphoric acid, $HNP(SH)_3$; ammonium nitrilodithiophosphate, $(NH_4S)_2PN$; thiophosphoric nitrile, NPS; and by heating phosphorus pentasulphide in a current of ammonia at 850°. The purified pentasulphide was first sat. with dry purified ammonia at ordinary temp., and the product heated in an atm. of ammonia till the Jena glass containing tube began to soften; the complex mixture of ammonium thiophosphates so obtained was heated for 12 hrs. at 850° in a current of ammonia, or the products of its decomposition. Phosphorus nitride of a high degree of purity remained. A. Stock and H. Güneberg found that phosphorus heptasulphide gave a poor yield, and phosphorus trisulphide none. The product obtained by heating a mixture of pentasulphide and ammonium chloride is impure. A. Stock and co-workers found that the nitride is formed among the products of the action of liquid ammonia on ordinary phosphorus or phosphorus dihydride, P_4H_2; or by heating the ammino-compounds of solid phosphorus hydrides.

Phosphorus nitride is without taste or smell. Its colour may be white, or may vary from white to dark red according to the time it has been heated above 850°. The film of red phosphorus sometimes observed on the surface has no perceptible influence on its composition. A. Stock and H. Grüneberg gave for the sp. gr. at 18° the value 2·51; H. Herzer, 2·495 for the sp. gr. at 25°/4°; 65·2 for the mol. vol.; and 910° for the temp. of decomposition; and A. Stock and F. Wrede, +81·5 Cals. for the heat of formation per mol of P_3N_5 from ordinary phosphorus, and +70·4 Cals. from red phosphorus; the mol. heat of combustion is 473·2 Cals. at constant vol., and 474·7 Cals. at constant press. A. Stock and B. Hoffmann could find no solvent for the nitride. A. Stock and H. Grüneberg said that the nitride is chemically inactive at ordinary temp., but at a high temp. it acts as a powerful reducing agent in consequence of its dissociation into phosphorus and nitrogen which begins in vacuo at 760°. According to A. Stock and co-workers, when the nitride is heated to redness in *hydrogen* it furnishes phosphorus and ammonia; it burns when heated in *oxygen;* at ordinary temp. *water* has little or no action, while boiling water slowly decomposes it into ammonia and phosphoric acid: $P_3N_5+12H_2O=3H_3PO_4+5NH_3$; F. G. Liljenroth proposed to utilize this reaction in the manufacture of ammonia. The decomposition by water in a sealed tube at 180° is quantitative after a few hours' action. Aq. soln. of all kinds, including conc. *nitric acid*, have no action. When heated in *chlorine*, the nitride takes fire at the temp. of softening glass. When heated with many *metals*—*e.g.* magnesium—phosphides are formed. It reduces *metallic oxides*—*e.g.* lead oxide at a dull red-heat gives lead; and arsenic trioxide, arsenic; the reduction of antimony trioxide proceeds with difficulty; and zinc oxide, at the softening temp. of glass, is not changed.

I. A. Bachman[20] found that no signs of **arsenic nitride,** AsN, were obtained by heating arsenic trioxide to 300°–350° in an atm. of ammonia; but if a sealed tube containing silver cyanide and arsenious oxide be heated at this temp., a dark brown substance is formed as a coating over the crystals of arsenic trioxide. The brown substance contained only a little carbon, and was considered to be the impure nitride. F. Fischer and F. Schröter prepared arsenic nitride by the process indicated in connection with Fig. 11. C. Hugot prepared arsenic nitride by rapidly heating arsenic imide in vacuo at 250° : $As_2(NH)_3=2AsN+NH_3$. The orange-red product is decomposed into its elements at a temp. not far distant from its temp. of formation. I. A. Bachman said that the nitride gives off ammonia when heated with soda-lime; it dissolves partially in alkali-lye; and dissolves completely in strong acids. F. Hérard [21] found that when antimony is heated to dull redness in a current of nitrogen, greyish vapours are evolved. K. Iwase found that nitrogen is not dissolved by antimony. E. C. Franklin [22] reported an impure antimony nitride to be formed by the action of antimony iodide on potassium amide in liquid ammonia soln. which condenses on the cool parts of the tube in agglomerations of amorphous antimony. The fact that the amorphous variety of antimony is not produced in a current of nitrogen is taken to indicate that **antimony nitride,** SbN, is formed which decomposes in the cooler parts of the tube. F. Fischer and F. Schröter obtained the impure nitride as a black powder by the method indicated in connection with Fig. 11. The nitride decomposed explosively when heated depositing a mirror of antimony on the containing tube. When treated with dil. hydrochloric acid, antimony and ammonium chlorides were formed: $SbN+4HCl=SbCl_3+NH_4Cl$. F. Fischer and co-workers prepared **bismuth nitride,** BiN, by the method indicated in connection with Fig. 11. E. C. Franklin prepared it by the action of bismuth tribromide or triiodide on potassamide in liquid ammonia soln.: $BiI_3+3KNH_2=BiN+3KI+2NH_3$. The dark brown precipitate becomes almost black on drying, and gradually decomposes on standing—when the dry precipitate is heated with dil. hydrochloric acid some bismuth always remains. The dry nitride explodes when treated with water or dil. acids. It is slowly decomposed by water vapour. F. Fischer and F. Schröter said that explosion occurs when the dry nitride is shaken and the walls of the containing tube become covered with a mirror of bismuth.

H. E. Roscoe [23] showed that what J. J. Berzelius had reported to be metallic vanadium was really a nitride. Three nitrides have been reported, V_2N, VN, and VN_2. There is a doubt whether or not the first two substances are the same. H. Mehner obtained the nitride by heating a mixture of carbon and vanadium oxide in an atm. of nitrogen. I. I. Shukoff observed no reaction between nitrogen and vanadium at 1250°. G. Tammann noted the formation of a film of nitride when vanadium is heated in nitrogen; and C. Setterberg obtained an impure nitride during the electrolysis of a soln. of ammonium vanadate. H. E. Roscoe prepared **vanadium mononitride,** VN, by passing ammonia over vanadyl trichloride contained in a bulb tube and heated until all the ammonium chloride had been expelled; the remaining black powder was heated to whiteness in a platinum boat in a current of ammonia for several hours. It was also obtained by heating for a long time ammonium vanadate to whiteness with the exclusion of air; by heating vanadium trioxide to whiteness in a current of ammonia; and by heating vanadium in nitrogen. E. Friederich and L. Sittig made it by heating the oxide in hydrogen and nitrogen gases; and A. E. van Arkel, by heating the metal filament in an atm. of nitrogen. The greyish-brown powder is not altered at ordinary temp. in air, but when heated, it forms blue vanadium oxide, VO_2, and at a higher temp., vanadium pentoxide. It loses nitrogen when heated in hydrogen; and evolves ammonia when heated with soda-lime. N. Whitehouse, however, found that at 400°, water vapour forms ammonia and vanadium oxide. K. Becker and F. Ebert found that the X-radiogram corresponded with a cube of side 4·28 A., and density 5·46. E. Friederich and L. Sittig found the space-lattice is a face-centred cube of the sodium chloride type with side 4·28 A. There are four mols. per unit cell. The sp. gr. is 5·63; the m.p. is about 2050°; and it decomposes but does not sublime at the m.p. R. E. Slade and G. I. Higson said that the dissociation press. of vanadium nitride at 1203° does not exceed 0·2 mm., and at 1271° does not exceed 1·5 mm. The respective heats of formation are 79·2 Cals. and 77·2 Cals. The electrical resistance is 2×10^{-4} ohm at ordinary temp., and $8{\cdot}5\times10^{-4}$ ohm at the m.p. E. Wedekind and C. Horst gave $4{\cdot}13\times10^{-6}$ for the magnetic susceptibility.

W. Muthmann and co-workers also reported that finely divided vanadium reacts with nitrogen at a red-heat. The reaction is so slow that 20–24 hrs. are needed for the increase in weight to become constant; nitrogen is also absorbed at dull redness, but the action is still slower. In contradistinction to H. E. Roscoe, the composition of the product approximated **vanadium heminitride,** V_2N. R. E. Slade and G. I. Higson found that vanadium nitride dissociates at 1203° and 0·2 mm. press. According to N. Whitehouse, at a white-heat vanadium forms the mononitride. The velvety-black powder is unchanged in air; when heated in air, however, it forms vanadium pentoxide; water, and dil. hydrochloric acid, hot or cold, have no action, but it dissolves in cold dil. nitric acid. G. Gore found that vanadium nitride is insoluble in liquid ammonia. It is not affected by alkali-lye, but with fused potassium hydroxide, ammonia is evolved.

In 1858, **vanadium dinitride,** VN_2, was prepared by E. Uhrlaub, but a wrong formula was given to it owing to an erroneous value for the at. wt. having been used in calculation. Both H. E. Roscoe, and E. Uhrlaub obtained it by heating vanadyl chloride in a current of dry ammonia until most of the ammonium chloride had volatilized, as in the case of the mononitride, but instead of raising the temp. to whiteness, the product was washed in ammoniacal water, and dried in vacuo over conc. sulphuric acid. The black powder so obtained loses nitrogen when heated, and passes into the mononitride; when exposed to air, ammonia is evolved and the vanadium is oxidized. With molten potassium hydroxide, ammonia is developed; sodium hydrochlorite gives nitrogen; nitric acid in the cold does not attack this nitride, but when heated the attack is vigorous. E. Uhrlaub, and A. Safarik found about 0·1 per cent. of hydrogen in the compound.

H. Moissan[24] found that when powdered columbium is heated to 1200°, in nitrogen, the metal becomes coated with yellow *niobium nitride* or **columbium tritapentanitride,** Cb_3N_5, but at 500°–600°, there is no perceptible action. L. Weiss and O. Aichel observed that when columbium is heated in air, both oxide and nitride are formed. H. Moissan also observed that finely powdered columbium dissociates ammonia at a red-heat without changing in weight; and W. von Bolton showed that when columbium is heated in ammonia, the metal becomes matte and greyish-brown, and gives off ammonia when heated with potassium hydroxide, showing that some nitride was formed. H. Rose prepared a nitride by heating columbyl chloride in a current of ammonia. A. Joly said that this product shows all the properties of a mixture of columbic oxide and nitride. H. St. C. Deville, H. Rose, and A. Joly found that a nitride corresponding, according to H. St. C. Deville, with **columbium mononitride,** CbN, is formed when columbic oxide is heated to a high temp. in a current of ammonia. E. Friederich and L. Sittig obtained the mononitride by heating a mixture of the oxide and carbon in nitrogen gas; and they said that the space-lattice is a face-centred cube of the sodium chloride type with side 4·41 A., and four mols. per unit cell. The sp. gr. is 8·4; the m.p. 2050°, and it decomposes but does not sublime at the m.p. E. Friederich gave 3070° for the m.p. W. Muthmann and co-workers obtained the pentatritanitride by heating the hydride to redness in a current of nitrogen. R. D. Hall and E. F. Smith obtained the pentatritanitride by the action of dry ammonia on an ethereal soln. of columbium pentachloride. K. Becker and F. Ebert found the X-radiogram corresponded with an elementary cube of side 4·41 A., and density 8·26. W. Muthmann and co-workers found that the pentatritanitride is a black powder which is stable in air, but burns when heated, forming columbium pentoxide. The nitride is not attacked by boiling water; nor is it decomposed by nitric acid, conc. sulphuric acid, or hot hydrochloric acid—it is only attacked by acids which can dissolve columbium. Boiling alkali-lye does not attack the nitride, but with fused potassium hydroxide, at dull red-heat, ammonia is evolved.

According to A. Sieverts and E. Bergner, tantalum nitride is slowly formed when tantalum is heated in nitrogen gas above 900°; but G. Tammann observed no reaction between nitrogen and tantalum at 700°. A. Joly, and H. Rose also obtained a nitride of undetermined composition by the prolonged action of ammonia on tantalum pentoxide. A. Joly reported **tantalum tritapentanitride,** Ta_3N_5, to be formed when ammonia is passed for some time into cold tantalum pentachloride, and heating the product up to a temp. sufficient to volatilize the ammonium chloride. The amorphous red powder when heated in air quickly forms tantalum pentoxide; when heated with cupric oxide, copper and nitrogen are formed; and when fused with potassium hydroxide, ammonia is evolved. A. Joly showed that if this nitride is heated to whiteness in a current of ammonia, nitrogen is evolved and black **tantalum mononitride,** TaN, is formed. E. Friederich and L. Sittig made it by heating the oxide in a current of nitrogen and hydrogen; and A. E. van Arkel, by heating a filament of the metal in nitrogen. K. Becker and F. Ebert found that the X-radiogram corresponded with hexagonal symmetry and an elementary parallelopiped of side 3·61 A.; A. E. van Arkel gave 3·05 A., and for the axial ratio $a : c = 1 : 1{\cdot}62$. According to W. Muthmann and co-workers, **tantalum dinitride,** TaN_2, is formed when the metal is heated in nitrogen gas to 1000°. R. E. Slade and G. I. Higson found that the dissociation press. of tantalum nitride, at 1170°, is 0·4 mm.; and the heats of formation, 74·7 and 79 Cals. respectively. The properties of tantalum nitride resemble those of columbium pentatritanitride.

According to H. St. C. Deville,[25] **columbium carbonitride,** mCbN.nCbC, is formed when sodium columbate is heated to 1200° in a graphite crucible. A. Joly made it by heating a mixture of columbium pentoxide, carbon, and sodium carbonate (4 : 1 : 1) in a carbon crucible at a high temp.; and by the action of ammonium cyanide on columbium pentoxide at a high temp. The analyses of A. Joly varied from $m : n = 2 : 3$ to $1 : 5$. The greyish-violet or olive-green mass of acicular crystals burns in air or oxygen at a high temp.; chlorine transforms it into columbium pentachloride, carbon tetrachloride, and carbon—not columbium oxytrichloride; copper or lead oxide is vigorously reduced. H. Rose found that freshly prepared, hydrated columbium pentoxide, when heated to redness in cyanogen, furnishes black pulverulent **columbium oxycarbonitride,** $Cb_2O_5N_5C$. It conducts electricity well; it oxidizes slowly when heated in air; and gives off ammonia when treated with fused potassium hydroxide.

For *sulphur nitride,* see nitrogen sulphide; for *selenium nitride,* see nitrogen selenide; and for *tellurium nitride,* see nitrogen telluride. J. von Liebig[26] obtained a brown powder by igniting chromium chloride in ammonia, and he thought the product was elemental chromium. A. Schrötter showed that the product is **chromium nitride,** Cr_2N_2 or CrN.

According to A. Schrötter, the chromic chloride should be prepared as free as possible from oxide, and from water by heating it in a glass tube on an oil-bath until no more water is evolved. The tube is then cooled, and ammonia passed for a time. The tube is then heated, and ammonia passed until no more ammonium chloride is evolved. The cold mass is removed from the tube, crushed to small fragments, and again treated with ammonia. This operation is repeated several times.

A. Schrötter obtained a similar product by the action of ammonia on chromochloric acid, and C. E. Ufer said that the product then contains oxygen. H. N. Warren, E. Oliveri-Mandala and G. Comella, R. Kraus, C. E. Ufer, and E. Uhrlaub also prepared the nitride by the action of ammonia on chromic chloride; and the two last-named also made it by heating a mixture of ammonium and chromic chlorides: $CrCl_3 + NH_4Cl = 4HCl + CrN$. According to C. E. Ufer, if potassium dichromate, mixed with ammonium chloride, be melted under a layer of sodium chloride, only chromic oxide is formed; but G. B. Frankforter and co-workers said that a nitride is probably formed. F. Briegleb and A. Geuther obtained this nitride by heating chromium in an atm. of nitrogen;

and J. Férée, by heating pyrophoric chromium in an atm. of nitrogen. H. Hardtung gave 1200° for the temp. of formation. G. Tammann made some observations on the reaction. E. Baur and G. L. Voerman found that the reaction $2Cr+N_2\rightleftharpoons 2CrN$ is reversible. H. Herzer found the sp. gr. to be between 5·796 and 5·800 at 25°/4°; and the mol. vol. 11·4. E. Baur and G. L. Voerman found on heating the nitride at 790° ± 10°, the press., p mm., to be:

	0	3	9	21	37	59	180	4140 mm.
p .	174·5	172·5	170·5	166·5	152	157	139·5	126 mm.

They did not measure the dissociation press. at higher temp., and added that the dissociation does not proceed until a definite dissociation press. has been attained and then ceases as is commonly the case; rather does the dissociation press. exhibit a continuous slow change. This is explained by assuming that chromium and its nitride form not two phases, but only one variable phase. J. Férée made the nitride contaminated with a little oxide by heating pyrophoric chromium in a current of nitric oxide; and he also obtained this nitride by the action of ammonia on heated chromium.

E. Uhrlaub said that **chromium tritadinitride**, Cr_3N_2, is formed by heating the mononitride, CrN, in a current of ammonia; and G. G. Henderson and J. C. Galletly, reported this same oxide by heating chromium in ammonia at 850°. It was said to be black, and very indifferent towards chemical agents. It is oxidized when heated in air, or when melted with sodium dioxide. Nitric acid or aqua regia attacks it slowly.

A. Smits obtained the mononitride, CrN, by the action of chromic chloride on magnesium nitride; and A. Guntz, by the action of potassium chlorochromate on lithium nitride. Chromium nitride is a brown or black amorphous powder which C. E. Ufer found partially to decompose into its elements at about 1450°. E. Wedekind and T. Veit said that the nitride is not affected by an ordinary horse-shoe magnet, but is affected by a large electromagnet. I. I. Shukoff showed that the electrical conductivity of the powdered nitride, 12·72 to 15·40 mhos, is of the same order as that of the metals, and he therefore concluded that the so-called nitrides are only solid soln. of nitrogen and chromium, and not true chemical compounds. E. Baur and G. L. Voerman observed that chromium nitride is a very efficient catalytic agent in the decomposition of ammonia, whilst it has no effect in promoting the synthesis of ammonia. Hence, it was called a one-sided catalyst—*ein einseitiger Katalysator*. E. Baur and G. L. Voerman said that chromium nitride is much more stable than iron nitride, and is not reduced by *hydrogen*, even at 560°, 13 atm. press. C. E. Ufer found that when heated to redness in *air*, the nitride oxidizes with incandescence to form green chromic oxide; and A. Schrötter, and C. E. Ufer showed that it inflames in *oxygen* at 150°–200°, and burns to chromic oxide with a red light and the evolution of nitrogen. A. Briegleb and A. Geuther's nitride burned with difficulty in oxygen. C. E. Ufer said that the nitride is not attacked by *water*, or steam at 220°. It is not attacked by cold *chlorine*, but when heated in that gas, there are some small detonations at the beginning attributed to the possible formation of nitrogen chloride—a brownish-black sublimate, and violet chromic chloride, while nitrogen is evolved. Dry *hydrogen chloride* at a red-heat acts slowly without the evolution of a gas: $CrN+4HCl=CrCl_3+NH_4Cl$. An aq. soln. of an *alkali hypochlorite* reacts in the cold, forming an alkali chromate, and nitrogen; the nitride mixed with *potassium chlorate* detonates violently when heated. Dil. *acids*, and hot or cold conc. *nitric, hydrochloric, and hydrofluoric acids* are without action; boiling *aqua regia* dissolves it with difficulty; conc. *sulphuric acid* reacts slowly without the evolution of a gas, forming red chromic and ammonium sulphates. Dil. hot or cold *alkali-lye* has no action on the nitride; and when fused with *potassium hydroxide* at 190°, in a sealed tube, it forms only a trace of chromate, and gives off no ammonia. J. Férée said that when heated with *soda-lime* it gives off ammonia. C. E. Ufer found that the nitride could be heated for many hours with melted *sodium carbonate* in a covered crucible without change—if air has access, traces of chromate are formed. It detonates in contact with molten *potassium nitrate* giving off nitrogen but no red fumes.

F. Wöhler[27] obtained a **molybdenum nitride** of undetermined composition by heating together a mixture of ammonium and molybdenum chlorides. The black product gave off ammonia when treated with fused potassium hydroxide. G. G. Henderson and J. C. Galletly found that molybdenum reacts with ammonia at 850°, more slowly than chromium, and only a small proportion of a nitride is formed; and I. I. Shukoff observed a slight absorption of nitrogen at 780°; but G. Tammann observed none at 700°. W. Lederer obtained a molybdenum nitride from an arc between molybdenum electrodes in an atm. of nitrogen or of ammonia. The Badische Anilin- und Soda-fabrik heated molybdenum oxy-compounds in the presence of reducing gases mixed with nitrogen under press., and obtained the nitride—*e.g.* molybdenum trioxide at 500°–600° in an atm. of equal parts of nitrogen and hydrogen under 60 atm. press. I. Langmuir also observed that when a molybdenum filament is heated to about 2000°–2400° K., in nitrogen at 0·03 mm. press., the filament loses weight, and the nitrogen disappears. A deposit of molybdenum containing nitrogen collected on the walls of the bulb. The rate of disappearance of the nitrogen is independent of the press. when the latter exceeds one bar; the amount of nitrogen thus disappearing is much less than the chemical eq. of the molybdenum evaporated, and the ratio, ϵ, of the number of mols. of nitrogen removed to the number of atoms of molybdenum evaporated in the same time decreases from a maximum of about 0·4 to a minimum of about 0·01 as the temp. of the filament or bulb is raised. With very minute press. of water-vap., such as result even in presence of drying agents from failure to "bake out" the bulb, no complete removal of nitrogen occurs, although under such conditions molybdenum will remove carbon monoxide and tungsten will remove either nitrogen or carbon monoxide, the value of ϵ in each of these cases being unity. The fact that ϵ is independent of the press., but dependent on the filament and bulb temp., indicates that the reaction occurs in the space around the filament, and that each collision between molybdenum atoms and nitrogen mols. results in combination, at least two products being formed; these are probably a first-order compound of the formula NMoN and a second-order compound, $Mo : N_2$, the proportion between the amounts of these two depending on the relative velocity of the mols. at the moment of collision and on the internal velocity of the nitrogen mols. The former compound is very stable and cannot be decomposed on the bulb by heating to 360°, its formation being favoured by low relative translational velocity of the colliding mols. and by high internal or rotational velocity in the nitrogen mol. All those collisions which do not yield a first-order compound give one of the second order which is so unstable that it decomposes practically completely on striking the bulb, owing to the attractive forces between pairs of molybdenum atoms being much greater than between these and nitrogen mols. The deposit which collects on the bulb has the following properties. It is spongy and can easily be rubbed off with the finger on opening the bulb, whereas deposits formed in a high vacuum are dense and can scarcely be scratched off with a knife. If the bulb is kept at the temp. of liquid air, the deposit formed gives up some nitrogen when warmed to the ordinary temp., but only part of this nitrogen is absorbed again on cooling the bulb; the larger part of the nitrogen in the deposit is not, however, liberated by heating in a vacuum at 360°. The deposit very rapidly absorbs up to about one-thirteenth of its chemical eq. of nitrogen when cooled by liquid air, but it does not readily absorb hydrogen under these conditions. At the ordinary temp., or above, however, large quantities of hydrogen are absorbed or dissolved by the deposit, these being given up slowly at 300° in a good vacuum. When heated in nitrogen at 270° or above, the deposit combines with nitrogen, and this is not given off again at 360° in a vacuum. The deposit reacts rapidly with water-vap., at the ordinary temp. with production of hydrogen, much of which remains dissolved in the deposit until liberated by heating at 360° in vacuo. It is probable that the molybdenum is in an atomic state of division as a result of being deposited atom by atom by the decomposition of the unstable compound formed in the "unsuccessful collisions." Molybdenum deposited on the bulb in a high vacumu does not exhibit any of these characteristics. A. Rosenheim and H. J. Braun prepared **molybdenum tritadinitride,** Mo_3N_2, by heating molybdenum trichloride in ammonia at 760°; and E. Uhrlaub, by heating molybdenum trichloride in dry ammonia on a gradually rising temp. The analyses of the greyish-black product corresponded with **molybdenum pentitatrinitride,** Mo_5N_3; and after heating to a higher temp., the composition corresponded with **molybdenum pentitatetranitride,** Mo_5N_4. E. Uhrlaub using an old at. wt. determination represented the composition Mo_3N_2. At a white-heat, the end-product is molybdenum. H. Herzer gave 8·036 to 8·046 for the sp. gr. of Mo_3N_2 at 25°/4°; and 39·3 for the mol. vol.

According to F. Wöhler,[28] a black, pulverulent tungsten nitride is formed when the vapours of tungsten and ammonium chlorides are passed through a red-hot tube; and also when tungsten trioxide is heated in cyanogen. I. I. Shukoff observed no absorption of nitrogen by tungsten at 1250°; and G. Tammann, none at 700°. I. Langmuir observed similar phenomena with tungsten filaments at 3000° K. as those observed in the case of molybdenum filaments. When a tungsten lamp containing nitrogen, at a low press., is run for some time the nitrogen gradually disappears, and the disappearance is brought about in three ways: (i) Chemically by the formation of **tungsten dinitride,** WN_2; (ii) Electrochemically—when an electric discharge passes through nitrogen and a hot tungsten cathode is used, the nitride WN_2 is formed at the cathode; (iii) Electrically—at very low press. and high voltages there seems to be a reversible removal of limited quantities of nitrogen, in which the nitrogen is driven on to the glass in such a form that it can be recovered by heating. From zero press. up to about 0·001 mm. the rate of removal of the nitrogen is proportional to the product of the rate of evaporation and the press. of nitrogen. From about 0·003 mm. up to about 1 mm., the rate is directly proportional to the rate of evaporation, and independent of the press.; above press. of 2 mm., there is still direct proportionality between the rate of removal and the rate of evaporation, but the latter is materially reduced by the presence of the gas. The nitride, WN_2, in thin layers is a clear, brown colour, very different in appearance from finely divided tungsten. C. J. Smithells and H. P. Rooksby gave 6·3 for the sp. gr. The dinitride is stable in a vacuum at 400°, but is decomposed at 2400° K. It is decomposed by water, giving ammonia and probably the oxide WO_3. Nitrogen does not, at any temp., react perceptibly with solid tungsten. The behaviour of nitrogen towards solid tungsten and tungsten vapour is similar to that of oxygen towards platinum and platinum vapour. G. G. Henderson and J. C. Galletly found that heated tungsten decomposes ammonia, but virtually no nitride is formed. H. Hardtung gave 1365° for the temp. of formation. R. Pörscke and A. Rathjen observed the formation of a nitride when the tungsten filament of an electric lamp is heated in ammonia. E. Uhrlaub reported the formation of **tungsten tritadinitride,** W_3N_2, when tungsten tetrahydrohexanitride, $W_3N_6H_4$, is heated in ammonia; and S. Rideal, **tungsten hemitrinitride,** W_2N_3, by heating tungsten chloride or oxychloride in ammonia. The black, lustrous powder can be freed from ammonium chloride by washing. H. Herzer gave 12·083 to 12·120 for the sp. gr. at 25°/4°; and 33·8 to 33·9 for the mol. vol. When heated in air, this nitride furnishes tungsten trioxide. Conc. sulphuric acid oxidizes it to tungstic acid and ammonium sulphate. It is insoluble in nitric acid, dil. sulphuric acid, and soda-lye; it gives off ammonia when treated with fused potassium hydroxide; and aqua regia oxidizes it to tungstic oxide.

C. F. Rammelsberg[29] found that dry ammonia reduced uranium tetrachloride to the trichloride, giving off nitrogen; and E. Uhrlaub showed that if the tetrachloride be heated for some hours in ammonia gas, and finally in the vapour of ammonium chloride, a black nitride was formed. A. Colani also noted that if sodium chlorouranate be heated to redness in dry ammonia, a black crystalline nitride is formed. H. Moissan found that uranium unites directly with nitrogen at 1000°, or with ammonia at a lower temp., forming a yellow **uranium tritatetranitride,** U_3N_4. The same product was obtained by heating uranium carbide to 1100°, but the reaction was incomplete. E. Friederich and L. Sittig prepared uranium nitride in an impure state by heating a mixture of the oxide and carbon in nitrogen. V. Kohlschütter prepared uranium chloride by the action of chlorine on uranium carbide heated in a hard glass bulb-tube; and then passed ammonia over the heated product. The dark green crystals melted to a black liquid which became solid as the reaction progressed. The product contained chlorine, and oxidized when ground in a mortar for retreatment. No definite compound was obtained. He recommended preparing the tritatetranitride by reducing uranium oxide with aluminium or magnesium in an atm. of nitrogen: $16Al+3U_3O_8+6N_2=3U_3N_4+8Al_2O_3$. If magnesium be employed, the magnesium nitride and oxide are readily removed by washing with dil. hydrochloric acid. Uranium nitride is a stable compound which, when heated in air, furnishes uranium oxide, U_3O_8. H. Herzer gave 10·044 to 10·088 for the sp. gr. at 25°/4°; and 76·4 to 76·7 for the mol. vol. It is not attacked by conc. hydrochloric or sulphuric acid, but oxidizing acids quickly decompose it. It is not changed by alkali-lye, but gives off ammonia when fused with potassium hydroxide. H. Moissan's preparation was decomposed by boiling alkali-lye. O. Heusler found that nitrogen reacts with heated uranium carbide in three stages, first forming **uranium pentitadinitride,** U_5N_2, thus: $5UC_2+N_2\rightleftharpoons U_5N_2+10C$; then **uranium pentitatetranitride,** U_5N_4, thus: $U_5N_2+N_2\rightleftharpoons U_5N_4$; and finally tritatetranitride: $3U_5N_4+4N_2\rightleftharpoons 5U_3N_4$. Both the pentitadinitride and the pentitatetranitride are soluble in dil. hydrochloric acid and all the nitrogen goes into soln. as ammonia. A. Remelé noted that uranium nitride exhibits a photoelectric effect.

H. N. Warren[30] reported a manganese nitride to be formed by passing ammonia over heated manganese oxide, but O. Prelinger was unable to confirm this. A. Guntz observed a trace among products obtained on heating manganese in nitrogen peroxide. W. C. Heræus found that manganese in an atm. of nitrogen at 1210°–1220° probably forms a nitride; and N. Tschischewsky heated 97 per cent. manganese in an atm. of ammonia and found that the metal absorbed the following percentage proportions of nitrogen at different temp.:

	330°	400°	500°	550°	600°	700°	800°	900°	1000°	1100°	1200°
N_2 .	0·16	0·58	2·63	9·22	14·39	14·36	4·35	10·59	7·20	4·00	1·73

and with ammonia in place of nitrogen,

	400°	500°	600°	700°	800°	900°	1000°	1100°	1200°	1300°
N_2 .	0·08	0·37	1·41	3·2	5·48	7·3	7·8	5·23	3·29	1·55

The results are plotted in Fig. 15. G. Tammann observed a reaction at 700° between nitrogen and manganese. E. Wedekind and T. Veit obtained **manganese heptitadinitride,** Mn_7N_2, by the action of ammonia on manganese heated by the oxyhydrogen flame, and found it to have stronger magnetic properties than the dipentita- or ditrita-nitrides. It is readily attacked by acids and alkalies. O. Prelinger showed that when powdered manganese oxidizes in air, some nitride is formed, and that when finely divided manganese, obtained by heating the amalgam, is heated in an atm. of nitrogen, or when the mercury is driven from manganese-amalgam in an atm. of nitrogen, **manganese pentitadinitride,** Mn_5N_2, is formed. F. Haber and G. van Oordt said that this nitride, so formed, is a mixture of manganese oxide and the ditritanitride.

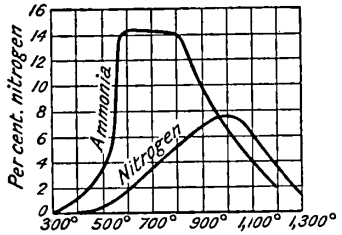

Fig. 15.—The Effect of Ammonia and Nitrogen on Manganese at Different Temperatures.

According to O. Prelinger, the dipentitanitride has a dull, metallic lustre, and, when finely divided, is somewhat darker than powdered manganese. On heating in a stream of hydrogen, ammonia is formed, whilst if hydrogen sulphide is substituted for the element, ammonium sulphide results. On treatment with ammonium chloride soln., ammonia, hydrogen, and the double chloride of manganese and ammonium are obtained: $Mn_5N_2+20NH_4Cl=12NH_3+2H_2+5(NH_4)_2MnCl_4$, and on fusion with caustic alkali much ammonia is liberated. When this nitride is heated in ammonia, it forms **manganese tritadinitride,** Mn_3N_2; and the same compound is formed if ammonia be substituted for nitrogen in the preparation of the preceding compound. H. Hardtung employed this process working at 760°–850° for 2–3 hrs. F. Haber and G. van Oordt, however, consider that this is the product of heating manganese-amalgam in nitrogen. G. G. Henderson and J. C. Galletly prepared this nitride by the action of ammonia on finely powdered iron at 800°. F. Fischer and co-workers made manganese nitride by the method indicated in connection with Fig. 11. According to O. Prelinger, the colour of the ditritanitride is the darker; it easily acquires a lustre under press.; its sp. gr. is 6·21 at 18°/4°. H. Hardtung gave 1000° for the temp. of formation, and 1100° for the temp. of decomposition. H. Herzer gave 550° for the temp. of decomposition. O. Prelinger said that manganese nitride behaves like the dipentitanitride towards hydrogen, hydrogen sulphide, and potassium hydroxide. I. I. Shukoff gave 18·18 to 22·62 mhos for the electrical conductivity of the powdered nitride. F. Haber and G. van Oordt studied the production of ammonia by the action of *hydrogen* on manganese nitride at 530°; and H. Hardtung, between 400° and 960°. A temp. of 850° was found to be most suitable. According to O. Prelinger, nitric acid dissolves manganese nitride only when hot; hydrochloric acid acts on it only in the presence of platinum; aqua regia dissolves it slowly; sulphuric acid acts only when hot, and with the conc. acid, sulphur dioxide is formed; acetic acid has no action; water slowly forms ammonia; potash-lye acts slowly in the cold, rapidly when heated, giving off ammonia; and when heated in nitrogen, the dipentitanitride is formed. H. Hardtung observed no evidence of the formation of cyanides by the action of carbon monoxide or dioxide on manganese nitride. E. Wedekind found that neither the dipentitanitride nor the ditritanitride shows any ferromagnetism when heated; but when cold the diheptitanitride is most magnetic, and the ditritanitride, least. O. Prelinger considers that manganese is quinquevalent in the dipentitanitride, and tervalent in the ditritanitride. I. I. Shukoff regarded the manganese nitrides as solid soln.

In 1808, A. B. Berthollet[31] found that when dry ammonia is passed over iron wire at a red-heat, the gas is decomposed into its elements, and the iron becomes very brittle, though it does not perceptibly increase in weight; L. J. Thénard said that the increase does not amount to 0·2 per cent.; and F. Savart added that after a 2 hrs.' passage of the gas, the iron appeared brittle; it exhibited the fine-grained fracture of steel and could be hardened like steel; but after 9 hrs.' passage, the metal was softer than common iron and no longer admitted of being hardened; the sp. gr. fell from 7·788 to 7·6637. C. Despretz, however, said that if ammonia, freed from moisture and carbon dioxide, be passed 6–8 hrs. over red-hot iron there is an increase in weight amounting to 7–11·5 parts per 100 parts of iron, and iron nitride is formed. This result was confirmed by H. Buff, F. Gröbe, A. H. Allen, G. J. Fowler, A. Rossel, G. T. Beilby and G. G. Henderson, A. H. White and L. Kirschbraun, E. B. Maxted, and G. Charpy and S. Bonnert.

An iron nitride occurs in nature. O. Silvestri found it as a very thin coating on the lava from the volcanic eruption at Mount Etna in 1874. The non-crystalline powder was silvery white; its sp. gr. was 3·147; it was slowly attacked by acids; and it had a composition corresponding with Fe_5N_2—some free iron was probably present. O. Silvestri called the mineral *siderazote;* and A. d'Achiardi, *silvestrite*—after its discoverer.

Nitrogen is slightly soluble in iron, and E. Jurisch showed that its solubility is proportional to the square root of the press. At 760 mm. press., 100 grms. of reduced iron absorbed

	878°	930°	981°	1033°	1084°	1136°
Mgrms. N_2. . . .	1·58	21·65	21·03	20·22	19·73	18·85

Absorption commenced at about 850°. A. Sieverts and W. Krumbhaar also showed that iron and steel absorb small quantities of the gas above 1200°. A. Sieverts found that when the reduced metal is continuously heated in the gas, a small amount is absorbed, and a little absorption was found to occur at ordinary temp. by A. W. F. Rogstadius, and F. Briegleb and A. Geuther. I. I. Shukoff detected no absorption of nitrogen by iron at 1250°. H. Braune found 0·02–0·062 per cent. of nitrogen in various samples of iron and steel. Grey pig iron had 0·002–0·020 per cent.; basic bessemer white pig iron, 0·020–0·030; basic open-hearth white pig iron, 0·025–0·035; forge white pig iron, 0·030–0·035; puddle bar for wire, 0·025–0·030; Swedish hearth iron, 0·006–0·008; basic open hearth steel, 0–0·030; acid bessemer steel up to 0·060. These numbers are probably all too high. This subject has been also discussed by B. Strauss, K. Iwase, A. Bramley, E. H. Schulz and R. Frerich, J. Petrén and A. Grabe, etc. According to J. H. Andrews, and A. W. F. Rogstadius, the absorption occurred when the metal is melted in the gas at a high press.; the former worked at 1000 atm. As indicated below, there is no evidence of the formation of a nitride by the direct union of the two elements, although many metallurgists—*e.g.* H. Braune, A. Pourcel, J. H. Andrews, and N. Tschischewsky—say that the absorbed nitrogen does form a nitride—if so, probably in the cooling metal, owing to the influence of other elements, and the action may be related to that which occurs during the formation of cyanides in the furnace. H. Wolfram found that pyrophoric α-iron begins to absorb nitrogen at 100°; and pure iron can retain 0·033 per cent. of nitrogen at its sintering temp. He found the following percentage proportions respectively in untreated iron and in iron after heating it in an atm. of ammonia: Purified iron, 0·0 and 0·033; skiegeleisen, 0·025 and 0·059; 80 per cent. ferromanganese, 0·039 and 0·46; manganese by the thermite process, 0·01 and 5·3; grey iron, 0·033 and 0·054; white iron, 0·011 and 0·017; steel, 0·022 and 0·03; phosphoriferous iron, 0·023 and 0·028; iron carbide, 0·035 and 0·045; ferronickel, 0·029 and 0·055; and ferrotungsten, 0·019 and 0·023. Hence, the presence of manganese particularly favours the absorption of nitrogen. According to E. Tilche, in the production of iron nitride and its subsequent conversion into ammonia by treatment with hydrogen, the gases are exposed to the action of a radioactive material, and the iron raised to a high electric potential and heated to redness during its treatment with nitrogen. I. Musatti and M. Croce studied the action of nitrogen during the cementation of steel. H. Braune said that the nitrogen in iron is exclusively combined with the ferrite, and not with the carbides; in ferrite the iron nitride is in solid soln. lowering the m.p., and the degree of solubility of the carbides. The absorbed nitrogen affects very materially the mechanical properties of the metal. Thus, J. H. Andrews found that 0·3 per cent. of nitrogen entirely suppresses the critical changes which occur in pure iron; and 0·25 per cent. of nitrogen and 0·6 per cent. of carbon lower the Ar_2-point, thus preserving the iron in the γ-form. N. Tschischewsky examined the effect of carbon, manganese, silicon, and aluminium on nitrogenous iron. H. Braune said that nitrogen increased the tensile strength of iron, and decreased the elongation; thus a steel with 1·15 per cent. of carbon had no elongation, and became entirely brittle with 0·030–0·035 per cent. of nitrogen. The results of some of N. Tschischewsky's experiments on the elastic limit and elongation of iron wires containing nitrogen are shown in Fig. 16. More nitrogen is required to make the elongation vanish, with steel containing less carbon. The hardness increases as the proportion of nitrogen increases; a rod of soft iron which had been heated to 800° in ammonia became so hard that it could be used as a drill; and a tube of malleable iron became so brittle that it could be broken by a blow from a hammer. H. Braune said that every 0·01 per cent. of nitrogen increases the electrical resistance of iron 3·23 per cent.; and it acts on the magnetic properties like additional carbon. The subject has also been discussed by H. le Chatelier, G. T. Beilby and G. G. Henderson, F. W. Harbord and T. Twynam, W. Giesen, C. E. Stromeyer, A. A. Blue, E. A. Sjösted, H. Herwig, P. Klinger, A. Fry, H. Tholander, L. Jordan and F. E. Swindells, A. Grabe, J. E. Johnson, L. E. Barton, W. E. Ruder and G. R. Brophy, G. F. Comstock and W. E. Ruder, A. E. White and J. S. Vaniek, and C. B. Sawyer. The relation of nitrogen and ammonia to the corrodibility of iron and steel has been discussed by O. A. Knight and H. B. Northrup, and H. E. Wheeler.

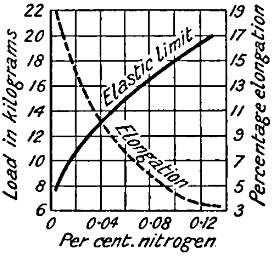

FIG. 16.—Elastic Limit and Elongation of Nitrogenous Iron.

In order to prepare the nitride, the iron should be in a finely divided condition, and a rapid current of ammonia, free from moisture and oxygen, should be employed. G. Tammann studied the reaction between nitrogen and iron. The most favourable temp. is 450°–475°. The nitride formed by the action of ammonia on iron has about 11 per cent. of combined nitrogen. This agrees with **iron heminitride,** Fe_2N, or Fe_4N_2. E. Frémy, and H. Herzer regard it as **iron pentitadinitride,** Fe_5N_2. The nitride is decomposed at 650°–670°. H. Hardtung found 450°–475° to be the most suitable temp. for the production of iron nitride. On the other hand, P. Herrmann said that at 1200° iron heminitride is formed quantitatively and readily. N. Tschischewsky found that with samples of iron, the maximum amount of nitride formed with purified iron is at 450°, Fig. 17, while pig iron and soft iron are sat. at about 600°. The higher proportion with sat. pig iron is not attributed to the action of carbon, but rather to "the finer state of the material." The retention of nitrogen by iron and steel is due to the presence of other impurities—*e.g.*, silicon, titanium, etc. The heminitride was made by E. Frémy, H. N. Warren, F. Girardet, and G. J. Fowler by heating ferrous chloride or bromide in ammonia. H. Hanemann used electrolytic iron foil; A. H. White and L. Kirschbraun, spongy iron; and G. J. Fowler, iron-amalgam. E. Frémy, and F. Briegleb and A. Geuther reported that at a dull red-heat iron can unite directly with nitrogen, but C. Stahlschmidt, and E. Baur and G. L. Voerman were unable to confirm this by working at ordinary press.; G. J. Fowler, by working with the iron and nitrogen in a sealed tube; and E. B. Maxted, by working at 2000 atm. press. D. Wolk, however, did say that if a mixture of barium and iron amalgams be quickly heated to 1000° in an atm. of nitrogen some iron nitride is formed. This statement, however, has not been confirmed.

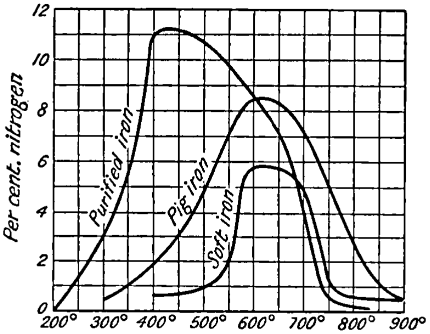

FIG. 17.—Effect of Ammonia on Iron at Different Temperatures.

The heminitride is completely decomposed above 600° when heated in nitrogen, below 600°, it possibly forms a more stable *iron tetritanitride*, Fe_4N. According to A. Fry, iron heminitride begins to break down at 440°, and on heating above that temp., it forms iron tetritanitride containing 5·9 per cent. of nitrogen. If the tetritanitride be heated to 560°, and cooled to 480°, it becomes magnetic. On heating to 630° magnetism again occurs, and is stronger the longer the heating period. The substance formed by the breaking up of the solid soln. with 0·5 per cent. nitrogen at 630°, undergoes a magnetic transformation at 740°. A. Fry represented his results by Fig. 18, where the region above *ABC* represents γ-iron; the lines *AFB* and *AEG* respectively denote the beginning and end of the separation of the solid soln. rich in iron; *GBH* represents the eutectic line with the separation of nitride-II (solid soln.-nitride needles); *DEF*, the magnetic transformation of nitrogenous ferrite; and *LM*, the magnetic transformation of the bodies produced by the decomposition of nitride-II. According to A. A. Noyes and L. B. Smith, if the equilibrium constant of the general reaction $2Fe_nN+3H_2=2Fe_n+2NH_3$ be expressed by K_1, and that of the reaction $N_2+3H_2=2NH_3$ by K_2, the dissociation press. of iron nitride can be expressed by K_1/K_2. The value of K_2 at 460°, calculated from known data, is $5{\cdot}10\times10^{-5}$. If the ratio Fe:N in the solid phase be greater than 9, the equilibrium constant $K_1=(P_{NH_3})^2/(P_{H_2})^3$ remains at 0·8–1·2, indicating probably the existence of a stable nitride, Fe_8N. When the Fe : N ratio becomes 7·7, the constant becomes 5·2 and increases to 30 with Fe : N=4·9 : 1; finally with Fe : N=2·6 : 1, the value of K_1 falls again to 2·1. These stages may correspond with the formation of metastable nitrides such as Fe_4N in solid soln. with the first, Fe_8N, or of two metastable nitrides such as Fe_6N and Fe_4N as separate solid phases; and finally of a stable nitride, probably Fe_2N. The dissociation press. of the nitrides in the above solid phases were calculated from K_1/K_2, and were found to be 20,000, 102,000, 590,000, and 41,000 atm. respectively. If, in the above reaction, complete equilibrium were established, all but about 0·1 per cent. of the ammonia would be dissociated, and the iron nitride, with its high dissociation press., would not form at all.

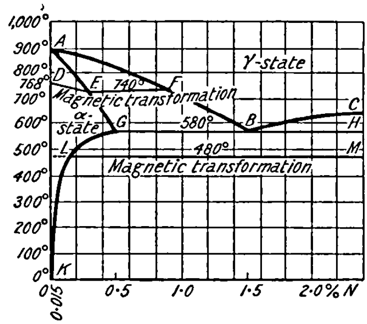

FIG. 18.—The System Iron-Nitrogen.

On heating iron in a current of ammonia at 680°, the tritacarbide, Fe_3C, present loses its total carbon and changes into the heminitride, Fe_2N. Two nitride layers are formed, the outer one, after quenching, contains over 8 per cent. nitrogen and consists of mixed crystals of heminitride, and the inner one consists of mixed crystals of the tritanitride. In the case of ordinary iron, these layers, though very hard, are too brittle to be of practical use. If, however, an alloy-steel with cobalt, vanadium, chromium, aluminium, titanium, or of chromium with one other element, is heated in ammonia at about 500°, more nitrogen goes into solid soln. than is the case with pure iron, and a very hard crust is obtained which does not flake off. The depth of the nitride layer is about 0·7 mm. The hardness cannot be increased by quenching, and is not reduced by slow heating to 440°. Above 560°, the nitride begins to decompose, and this is accompanied by a corresponding decrease of hardness. It is thought probable that from its mode of preparation, some unchanged iron would be present. The normal **ferrous nitride,** or **iron tritadinitride,** Fe_3N_2, was made by A. Guntz, by the action of lithium nitride on potassium chloroferrite; by using potassium chloroferrate, he obtained black-coloured **ferric nitride,** FeN. Iron tritadinitride may be pentitadinitride. F. W. Bergstrom prepared impure ferrous nitride by the action of ferrous tetramminothiocyanate on potassamide; and also by treating ferrous bromide with potassamide and then with a soln. of ammonium thiocyanate in liquid ammonia.

Iron heminitride is a dull grey powder which easily dissolves in dil. hydrochloric or sulphuric acid, forming ammonium and ferrous salts, and hydrogen. E. B. Maxted's arguments in favour of the view that the composition is Fe_3N_2 not Fe_4N_2(or Fe_2N), and that the so-called heminitride is a solid soln. of iron and the ditritanitride, $Fe_3N_2+Fe\rightleftharpoons Fe_4N_2$, as advocated by A. H. White and L. Kirschbraun, are: (i) nitrides with more nitrogen than is required for the latter formulæ are easily made; (ii) the mode of formation does not ensure the conversion of all the iron into nitride; (iii) the analogy with other nitrides; (iv) the existence of A. Guntz's Fe_3N_2, that is, Fe : N.Fe.N : Fe; and the transformation into ferrous and ammonium chlorides by the action of acids: $Fe_3N_2+Fe+10HCl=H_2+4FeCl_2+2NH_4Cl$; and $Fe_4N_2+10HCl=H_2+4FeCl_2+2NH_4Cl$. The mol. wt. of this nitride is unknown. The contained iron is therefore assumed to be in the bivalent state, and the nitrogen tervalent. The graphic formula, given by G. J. Fowler and P. J. Hartog, is:

$$\begin{matrix}Fe\\Fe\end{matrix}\!>N-N<\!\begin{matrix}Fe\\Fe\end{matrix}$$

G. J. Fowler gave 6·25 for the sp. gr.—C. Despretz's old value is 5·0. H. Herzer gave 6·985 to 6·992 for the sp. gr. at 25°/4°; and 44·0 for the mol. vol. G. J. Fowler and P. J. Hartog found the heat of soln. in dil. sulphuric acid to be 81·56 Cals., and the heat of formation, $2Fe+N_{gas}=Fe_2N+3\cdot4$ Cals. G. Charpy and S. Bonnerot showed that the nitride begins to decompose when heated to 500° in vacuo or in a current of nitrogen; and decomposition is rapid about 600°. This decomposition occurs under 18 atm. press., so that no formation of nitride is possible in nitrogen at these temp. H. Herzer gave 500° for the temp. of decomposition. E. Baur and G. L. Voerman found that when heated, the nitride decomposes into its constituents; at 350°, the dissociation is not perceptible; at 500°, the dissociation is very marked, and since at 600°, and 14 atm. press., no union of iron and nitrogen occurs, the maximum press. is greater than 14 atm. The reaction $2Fe_2N+3H_2\rightleftharpoons4Fe+2NH_3$ is reversible, and the equilibrium constant, $K=p^2/p_1{}^3$, where p denotes the partial press. of ammonia, and p_1 that of hydrogen. At 480° ± 3°, $K=6\cdot8\times10^{-4}$, and the dissociation press. is of the order 10^4 atm. As in the case of chromium nitride, the dissociation does not proceed until a definite dissociation press. has been attained, and then cease, rather does this press. exhibit a slow and continuous increase. This is taken to mean that iron and iron nitride do not form two constant phases, but rather one continuous phase. A. A. Noyes and L. B. Smith represent the system as one involving the reactions (i) $2Fe_xN+3H_2\rightleftharpoons2xFe+2NH_3$, where $(p_{H_2})^3K_1=(p_{NH_3})^2$; (ii) $N_2+3H_2\rightleftharpoons2NH_3$, where $pN_2(P_{H_2})^2K_2=(P_{NH_3})^2$, and it is known that $RT\log K_2=21400-11\cdot0T\log T+0\cdot00235T^2+22\cdot0T$, and for 460°, $T=460+273$, and $K_2=5\cdot10\times10^{-5}$; (iii) $2Fe_xN\rightleftharpoons2xFe+N_2$, where $P_{N_2}=f$ (solid phase). If all the reactions are in equilibrium, $P_{N_2}=K_1/K_2$. The equilibrium constant K_1 at 460° was found to vary with the proportion of nitrogen in the solid phase so that for

Ratio Fe : N . . .	17 : 1—9 : 1	7·7 : 1	4·9 : 1	2·6 : 1
K_1	1·0	5·2	30·0	2·1
Dissoc. press. P_{N_2} . .	20,000	102,000	590,000	41,000

These values of K_1 are taken to mean that there is first a formation of a nitride of small nitrogen content, say Fe_8N; then, either a metastable nitride as Fe_4N in solid soln. with the first one, or of two separate metastable nitrides as Fe_6N and Fe_4N as separate solid phases; and finally, of a stable nitride, say Fe_2N. By combining K_1 with K_2, the dissociation press. P_{N_2} were calculated. According to E. B. Maxted, iron nitride is only weakly magnetic; and the effect of various proportions of nitrogen on the magnetic properties of iron are illustrated by the curves, Fig. 18, showing the relation between the magnetic induction, B, and the magnetizing force, H; and Fig. 18, showing the relation between the permeability, μ, and the magnetizing force, H. E. Gumlich found the permeability of iron of the highest degree of purity to be 14,600 C.G.S. units.

E. Baur and G. L. Voerman studied the action of *hydrogen—vide supra*. According to G. J. Fowler, in *air* or *oxygen*, there is a very slight action at 120°; and oxidation is visible at 200°—brown ferric oxide is formed, but no nitrogen is oxidized; *water* vapour, at 1000°, produces a slow evolution of ammonia. A. Rossel prepared a nitride, which is readily decomposed by water, by heating a mixture of finely powdered calcium carbide and powdered iron while exposed to air. G. J. Fowler showed that very little if any nitrogen is oxidized during the simultaneous action of acids and *hydrogen dioxide.* The nitride takes fire spontaneously, or else on warming, when placed in *chlorine* gas—ferric chloride and nitrogen, but not nitrogen chloride, were formed—with chromate-water, iron and ammonium chlorides are formed. The attack of *bromine* is slow, even on warming, and ammonium bromide is formed. An ethereal soln. of *iodine* does not attack the nitride. Cold *hydrogen chloride* does not attack the nitride; chemical action begins about 220°, and is rapid at 350°, forming ferrous and ammonium chlorides. Dil. *hydrochloric and sulphuric acids,* as indicated above, dissolve the nitride, forming ferrous and ammonium chlorides. The attack by *hydrogen sulphide* begins about 200°: $2Fe_2N+6H_2S=4FeS+2NH_4HS+H_2$. The nitride is attacked by conc. *nitric acid* slowly—ammonium nitrate and nitrous and nitric oxides are formed. Oxidation of *nitric oxide* began about 120° and became rapid at 170°, and nitrogen is formed: $Fe_2N+2NO=2FeO+N_2$. No sign of the formation of cyanides was observed by heating a mixture of iron nitride and *carbon,* but if sodium be present, sodium cyanide is produced. There is a slight reaction with *carbon monoxide* at a red-heat, but no cyanogen was evolved; with *carbon dioxide* at 448°–538° some nitride is oxidized. No appreciable change occurred when iron nitride and *phenol* were heated in a sealed tube at 220°; and with *ethyl iodide,* no action was observed below 150°; and, at 200°–230°, the reaction appeared to be: $2Fe_2N+10C_2H_5I=2NH_4I+10C_2H_4+4FeI_2+H_2$. A neutral soln. of *copper sulphate* has no action on iron nitride, but if the soln. be slightly acidified, copper is precipitated and ammonium sulphate is formed.

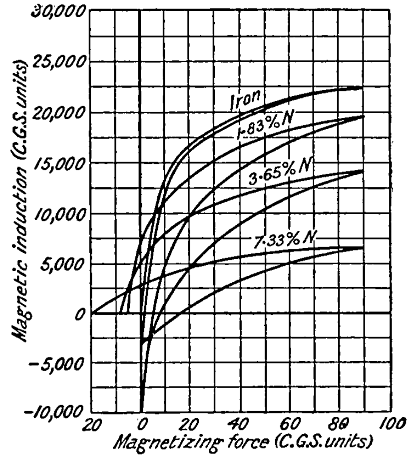

FIG. 19.—Relation between Magnetizing Force and Induction.

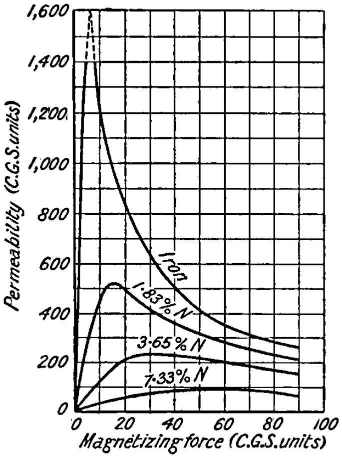

FIG. 20.—Relation between Magnetizing Force and Permeability.

E. Frémy[32] observed that **cobalt nitride** is not formed when cobalt sesquioxide or cobalt chloride is heated in ammonia gas; G. Tammann observed no reaction between nitrogen and cobalt at 700°. According to F. Vorster, the small observed increase in weight which occurs when powdered cobalt is heated in ammonia is really due to oxidation owing to the presence of traces of air. The cobalt, however, decomposes the ammonia into its elements; cobaltic hydroxide is not changed by ammonia gas at 170°; and an alcoholic or aq. soln. of ammonia in a sealed tube with cobalt sesquioxide produces no change. H. N. Warren said that when cobalt oxide or chloride is heated in ammonia gas, a nitride is formed. W. R. Hodgkinson and C. C. Trench heated cobalt sulphate in ammonia gas and observed the formation of an oxide and sulphide, but no nitride. E. St. Edme said that when cobalt is maintained at a red-heat for a considerable time in an atm. of nitrogen, the metal becomes passive towards nitric acid, presumably owing to the formation of a superficial film of cobalt nitride. A. Sieverts said that cobalt and nitrogen do not form a nitride at a temp. over 1150°. G. T. Beilby and G. G. Henderson heated cobalt in a current of ammonia, and starting the action at 470° and subsequently lowering the temp., they obtained a product with 10·33 per cent. of nitrogen. A. C. Vournasos allowed a mixture of cobalt cyanide and oxide to fall in small quantities at a time through an electric arc between carbon poles in an atm. of nitrogen. The brown product corresponded with **cobalt tritadinitride,** Co_3N_2. F. W. Bergström obtained cobaltous nitride, Co_3N_2, as a black solid, by heating cobaltous amide to 120°. It is almost unaffected by water. P. Herrmann said that powdered cobalt at 1300°, does not form a compound with either nitrogen or ammonia, but there is a marked volatilization of the metal. The metal in ammonia at 300° increases in weight, and when kept a long time at 250°, **cobalt tritanitride,** Co_3N, appears to be formed in very small amounts.

W. R. Grove obtained a product, thought to be **nickel nitride,** by the method he employed for zinc nitride. G. Tammann observed no reaction between nitrogen and cobalt at 700°. F. Vorster found that at 200°, nickel sesquioxide is reduced to nickel monoxide, and at a higher temp. to nickel; nickel hydroxide is not attacked by ammonia at 170°; and in a sealed tube at 150°, aq. ammonia slowly reduces nickel sesquioxide to nickel monoxide with the probable formation of nitric acid. In no case was nickel nitride produced. H. N. Warren believed he had produced nickel nitride by a process analogous to that used for cobalt nitride. P. Herrmann found that nickel chloride is reduced by ammonia at 500°, forming nickel. Finely divided nickel at 1400° does not react with either nitrogen or ammonia, but some metal is volatilized. At 50°, nickel powder absorbs some ammonia gas. When powdered nickel, or nickel chloride, is heated in a sealed tube with aq. ammonia, nickel hydroxide is formed, and in the absence of water, the nickel powder remains unchanged. P. Herrmann, and A. Smits obtained a black mass, probably nickel nitride, by heating dry nickelous chloride with magnesium nitride. G. T. Beilby and G. G. Henderson heated nickel in a current of ammonia at 500°, and obtained a product with 7·5 per cent. of nitrogen. A. C. Vournasos prepared **nickel tritadinitride,** Ni_3N_2, by a process similar to that used for the corresponding cobalt nitride. G. S. Bohart prepared the tritadinitride by heating nickelamide in vacuo at 120°. Nickel tritadinitride is a dull black powder which, under the microscope, consists of minute, roughly spherical particles. With steam at a red-heat, ammonia is evolved; and ammonia and hydrogen are evolved when the nitride is heated to redness in hydrogen. A. C. Vournasos said that the nitride burns in oxygen to nickel peroxide. It is soluble in dil. hydrochloric or sulphuric acid, forming nickel and ammonium salts. According to F. Wolfers, nickel is attacked by nitrogen at about 300°, producing a volatile nitride which is unstable at 600°. The volatile nitride is said to attack platinum.

F. Fischer and F. Schröter [33] said that the platinum metals do not form nitrides. G. T. Beilby and G. G. Henderson observed that while heating platinum in ammonia produced no **platinum nitride,** a profound change in the physical structure of the metal occurred; and G. G. Henderson and J. C. Galletly obtained a similar result with respect to **palladium nitride.** L. Arons believed that he obtained a fine sublimate of nitride when an arc is made between platinum electrodes in nitrogen. S. M. Jörgensen, and H. Wolffram obtained an explosive black powder, thought to be platinum nitride, by heating platinum ethylamminochlorides. L. Tschugaeff obtained indications of the formation of a platinum nitride in the reduction of potassium chloroplatinite with tertiary amines.

§ 13. The History of Ammonia

In the *Historia* of Herodotus (**4**. 181), written in the fifth century before our era, it is said that "there are pieces of salt in large lumps on the hills" of Libya, and the Ammonians, who lived there, "have a temple resembling that of Theban Jupiter." The first-century writers, Strabo, in his *Geographica* (**1**. 3, 4), and Dioscorides, in his *De medicinali materia* (**5**. 126), allude to this salt; while Pliny, in his *Historiæ naturalis* (**31**. 41, *c*. 77), referred to a variety of salt called *hammoniacum*—from *ἄμμος*—in allusion to its occurring in the sands; he also referred to the calcination of *nitrum* producing a "vehement odour." This shows that a number of salts were confused under one term (**2**. 20, 1). G. Apicius, in his *De re culinaria*, also written in the first century of our era, mentioned the use of *sal ammoniacum* in cooking; and a similar term was employed in the second century by Arrian, in his *Ἐγχειρίδιον*; in the fifth century by Simplicius, in his commentary on Arrian's *Enchiridion;* and about the same time by Ætius in his *Medicæ artis principes*. Dioscorides pointed out that *ἀμμωνιάκον* possessed a fibrous structure which enabled it to be readily divided, and to be thus easily distinguished from common salt. Nevertheless, in all these cases, H. Kopp[1] was able to say that *sal ammoniacum* was considered to be the same as rock-salt. The Latin translations of some of the Arabic writers of the eleventh and twelfth centuries—*e.g.* Albucases' or Alzaharavius' *Servitor;* Avicenna's *Fractatulus alchemiæ;* and Geber's *De investigione magisterii*—applied the term *sel ammoniacum* to what is now known as sal ammoniac. Basil Valentine speaks of sal ammoniac, Armenian salt, salt from Armenia, and Armenian sal ammoniac; and from the sixteenth century onwards, writers—A. Cæsalpinus, J. R. Glauber, G. Agricola, A. Libavius, F. Sylvius de la Boë, N. Lemery, etc.—used the term *sal ammoniacum* or *sal armeniacum* for ammonium chloride as distinct from sodium chloride, or for salts containing volatile alkali as distinct from those containing fixed alkali; and towards the end of the seventeenth century the term *sal ammoniac* was in almost general use for ammonium chloride. H. Kopp said that sal ammoniac was probably first brought to Europe from Asia Minor, where it occurred naturally, and was hence called *Armenian salt.* A. Cæsalpinus said that it was made *ex urina chamelorum.* The preparation was described in Geber's *De investigatione magisterii* somewhat as follows:

> Sal ammoniac is made from two parts of human urine, one part of the sweat (sudoris) of the same, one part of common salt, and one and a half parts of the soot of logs or sticks. When these have been heated together until the moisture is evaporated, true and useful sal ammoniac is sublimed. Mix the product with common salt and sublimate again, when the preparation is complete.

This mode of preparation reappeared in various forms in the works of later writers —*e.g.* N. Lemery, and A. Libavius. R. Boyle said:

> Though sal-ammoniac that is made in the East may consist in great part of camel's urine, yet, that which is made in Europe, and is commonly sold in our shops, is made from men's urine. . . . Sal-ammoniac might be made much cheaper if, instead of fetching it beyond the sea, our country-men made it at home; which it may easily be, and I am ready to give you the receipt, which is no great secret.

In 1716, C. Sicard, and in 1751, F. Hasselquist described the Egyptian method of making sal ammoniac; in 1719, L. Lemery showed how the salt was obtained directly from the soot collected in burning camel's dung; and in 1736, H. L. Duhamel du Monceau found that salt is not necessary in Geber's recipe, and that the soot is a purifying agent. In 1583, L. Thurneysser reported that sal ammoniac was made in Europe earlier than 834 A.D., but H. Kopp said that this report is given *mit seiner gewöhnlichen Lügenhäftigkeit.* Sal ammoniac was manufactured at Edinburgh in 1756, at Brunswick in 1759, and at Paris in 1770.

In the Latin translation of Geber's *Testamentum* there is a note: *De salibus animalium, piscium, volatilium, vegetabilium, et aliorium,* from which it appears to be highly probable that he obtained volatile alkali or liquor ammonia by heating some of these products, but he recorded no specific observations on this subject. In the fourteenth century, Raymond Lully, the assumed author of *Experimenta,* dated 1330, alluded definitely to aqua ammonia as *mercurius animalis* or *spiritus animalis,* for he said:

> Take in goodly quantity the early morning urine of boys from eight to twelve years of age. Place this in a glass alembic to completely putrefy. . . . See that the beak of the alembic is wide and open else the salt rising from the bottom of the alembic and sublimating will choke the neck of the beak. When they flow into the receiver, which if they do they will break the vessel, as happened in my case . . . you will clear out the salts with care and will keep them in a glass vessel well corked, for the salt is very volatile. . . . Beware of the fumes when opening the bottle, they are very pungent.

About the middle of the fourteenth century, Johann de Rupescissa, or Roquetaillade, referred to a substance which gave precipitates with metallic salt soln., and which was obtained by heating animal products in a closed vessel. Isaac Hollandus, a century later, called it *spiritus salis urinæ;* and this was followed by analogous allusions to this substance, by J. Mayow; A. Sala—*spiritus urinæ;* J. B. van Helmont—*spiritus salis lotii,* or *spiritis salis cruoris;* J. R. Glauber—*spiritus urinæ* or *spiritus volatilis salis armoniaci.* O. Tachen, R. Dossie, and A. Sala said that if *spiritus urinæ* (aq. ammonia) be mixed with *spiritus salis* (hydrochloric acid) the product is in all respects like ordinary sal ammoniac. This is considered to be the first direct synthesis of this salt (ammonium chloride). J. Kunckel inquired whence comes the causticity of the spirit of urine obtained when sal ammoniac is treated with quicklime, and considered that the causticity was carried from the lime to the volatile alkali during the treatment of the sal ammoniac. The term *spiritus urinæ* soon became *volatile salis ammoniaci;* and T. Bergman and others called it *ammoniacum.* Raymond Lully, R. Boyle, J. B. van Helmont, N. Lemery, F. Hoffmann, C. J. Geoffroy, J. Kunckel, etc., made various allusions to the properties of the substance obtained by heating sal ammoniac with acids, alkalies, or lime. Stephen Hales found that by heating of a mixture of sal ammoniac and lime in a retort, although he collected no gas, the water of the pneumatic trough was drawn backwards into the retort. In 1774, J. Priestley repeated the experiment, using mercury in his pneumatic trough, and thus definitely isolated ammonia gas which he named *alkaline air.* He said:

> It occurred to me that an alkaline air might be expelled from those substances containing volatile alkali. Accordingly, I procured some volatile spirit of sal ammoniac, and having put it into a thin phial, and heated it with the flame of a candle, I presently found that a great quantity of vapour was discharged from it; and being received in a vessel of quicksilver, it continued in the form of a transparent and permanent air, not at all congealed by cold.

For a time, it was thought that the volatile alkali, aqua ammonia, was a variety of fixed alkali, and that the latter could be converted into the former—*e.g.* L. C. Cadet de Gassicourt, and P. J. Macquer—but this hypothesis was no longer tenable after J. Priestley had isolated the gas, and shown that it could be decomposed by electric sparks so as to produce a combustible gas. In 1777, C. W. Scheele assumed that volatile alkali is a compound of nitrogen and phlogiston. In 1785, C. L. Berthollet found that when the gas is decomposed into its constituents by means of the electric spark, it furnishes approximately 0·725 vol. of hydrogen to 0·275 vol. of nitrogen, or 0·193 grm. of hydrogen to 0·807 grm. of nitrogen. More exact data were obtained by W. Austin, H. Davy, W. Henry, and A. B. Berthollet; but the general results confirmed the earlier observations of C. L. Berthollet. For ammonium, *vide* **4**, 31, 38.

§ 14. The Occurrence of Ammonia

A. Fowler and C. C. L. Gregory[1] found that many lines in the ultra-violet spectra of the sun and of ammonia are the same, and it was therefore inferred that ammonia is present in the absorbing atmosphere of the sun. The occurrence of ammonia in atm. air, and in rain-water, snow, and hail has been discussed in connection with atm. air. While spring waters usually contain little or no ammonia, river-water and sea-water may have appreciable amounts. Thus, J. B. J. D. Boussingault reported 0·016 to 4·9 mgrms. of ammonia per litre of river-water; and W. Knop, 0·7 to 2·35 mgrms. J. B. J. D. Boussingault found 2·0 mgrms. of ammonia per litre in the canal at Dieppe; A. Audoynaud, 0·16 to 1·22 mgrms. off Palavas, near Montpellier; L. Dieulafait, 0·221 mgrm. from the Mediterranean Sea, 12 kilometres from Marseilles; 0·204 mgrm. off Ismaila, 0·136 mgrm., in the Bay of Bengal, 0·340 mgrm. off the Coast of Cochin China; 0·176 off Socatora, off Cape Gardafuy, and in the waters of the Red Sea; E. Marchand, 0·57 mgrm. in the canal at Fécamp; A. Vierthaler, 13·8 mgrms. in the waters of the Adriatic Sea at Spalato; and T. E. Thorpe and E. H. Morton, 1·1 mgrm. in the waters of the Irish Sea. Observations were also made by J. Bouis, G. Forchhammer, A. Houzeau, W. Knop, L. Studdert, and A. Terreil. According to L. Dieulafait, ammonia occurs in the sea-water of all latitudes; and the proportion does not increase with the evaporation of the water, since some escapes into the air. J. Murray reported ammonia in the mineral waters of Cheltenham and Gloucester; A. Chevallier, in those of Passy and Chaudes Aigues; A. J. Béchamp, in those of Vergèze; F. Parmentier, in the bituminous waters of Clermont, etc. The ammonia in river-waters is sometimes derived from sewage, the organic matter of which, in the course of its decomposition, forms amino-acids, and then ammonium compounds. Ammonia is readily oxidized by certain organisms, forming nitrites and nitrates. The presence of ammonia is therefore often regarded as an indication of pollution by nitrogenous matters—*e.g.* urine.

L. Dieulafait[2] found ammonia in the deposits obtained during the evaporation of sea-waters, and he detected it in gypsum beds, and it is disengaged in the manufacture of plaster of Paris from gypsum. He said that all saline waters obtain their mineral matter from salt-bearing formations which contain a considerable quantity of ammoniacal salts. The ammonia which accompanies the boric acid emitted from the lagoons in Tuscany is said to be derived from the saline beds in which the boric acid occurs, the part played by the volcanic agent being purely mechanical. There is 0·07 mgrm. of ammonia per litre in the water of Lake d'Enghien, while the sulphur spring, fed by the lake, contains 5·06 mgrms. per litre. This is explained by assuming that the water from the lake passes over sediments from which it dissolves ammonium salts. Hence, added L. Dieulafait, all saline mineral waters ought to contain ammonium salts, whether these waters be sulphurous or not, thermal or not. A. Vogel reported ammonia in the rock-salt of Hall, Rosenheim, Friedrichshall, Orb, Kissingen, and Dürkheim. L. Glaser observed ammonia in the vicinity of a coal-deposit which had burnt at Duttweiler. The presence of ammonia in the vapours of the boric acid fumaroles of Monte Cerboli, etc., was noted by C. Blondeau, C. Schmidt, O. Popp, and H. St. C. Deville and F. Wöhler. Ammonium chloride was found in the vicinity of Hecla, by R. Bunsen; about the fumaroles of the Valley of Ten Thousand Smokes, Alaska, by E. T. Allen and E. G. Zies; and in the vicinity of Vesuvius, by A. Scacchi, and A. Ranieri. The subject was discussed by L. Palmieri, H. St. C. Deville, C. G. B. Daubeny, A. Gautier, and W. S. von Waltershausen. According to J. Stoklasa, the ammonium salts found on the lower portions of the lava of Vesuvius are not due to the burning of vegetation, because he found ammonia in lava at an altitude of 900 metres in places where no vegetation is present; in the sand of the crater; and in the gases streaming out of the crater. A. del Campo found ammonium fluoride in a sublimate from Chinyero, Canary Islands—*vide* ammonium chloride (**2.** 20, 16).

Soils readily adsorb gases of various kinds, and the occurrence of ammonia in soils has been discussed by W. Knop,[3] A. Mayer, A. Müntz and H. Coudon, E. Marchal, and M. Berthelot and G. André. The ammonia is derived from the decomposition of nitrogenous matter in the soil. P. Ehrenberg has discussed *Der Kreislauf des Ammoniakstickstoffs in der Natur*. C. G. Gmelin observed that ammonia is given off when some minerals are calcined. J. Bouis noted that most clays contain some ammonia. The ammonia in clays and ferruginous ores is supposed to have been absorbed from the atm. and partly derived from the oxidation of iron in contact with air and moisture. M. Faraday showed that clay which has been heated to redness, absorbed an appreciable quantity of ammonia from the air during eight days' exposure. J. B. J. D. Boussingault found that ferric oxide from the middle of a deep boring near Marmato contained ammonia. The presence of ammonia in iron ores, dolomite, clay, soil, and other porous substances has been noted by L. N. Vauquelin, A. Chevallier, M. Faraday, J. Bouis, W. Knop, A. Mayer, L. Dieulafait, and W. Austin. The occurrence of ammonia in iron-rust was noted by C. Bourdelin in 1683, and later, by L. N. Vauquelin, M. E. Chevreul, and J. Reiset; and M. Barré, and P. Regnard detected an odour of ammonia on breaking several ingots of steel, prepared by a special process, and gas escaped accompanied by a slight hissing noise. Analyses showed that the gas is mainly hydrogen and hydrocarbons—no ammonia or nitrogen was detected.

F. Sylvius de le Boë [4] noted the occurrence of ammonia in the juices of some plants—*e.g.* the spoon-wort. A. Pleischl found that the juices of many plants contain ammonia. E. Schultz and H. Schultze found it in the juice of the maple, birch, vine, and sugar-beet; and J. von Liebig, in tobacco juices. N. Castoro found ammonia in the embryo of plants. A. Hosaeus found ammonia in peas, and indeed in all the parts of plants he investigated; but, added E. Reichardt, the stalks of swallow-wort, and of corn, are free from ammonia in spring. H. Pellet said that ammonia is stored in some plants in the form of ammonium magnesium phosphate. E. Formanek,[5] and W. Kühne reported that the expired air of animals usually contains traces of ammonia. T. Rumpf, E. Hallervorden, W. Heintz, C. Neubauer, and C. M. Tidy and W. B. Woordmann showed that the urine of birds and reptiles has a large proportion of acid ammonium urate; and the urine of mammals contains a small proportion this salt. The presence of ammonia in blood was discussed by M. Nencki and co-workers, O. Hammarsten, H. Winterberg, S. Salaskin and co-workers, M. Jacoby, G. Dujardin, R. Beaumetz and A. Hardy, etc.

§ 15. The Preparation of Ammonia

The methods available for the preparation of ammonia can be conveniently arranged according to the source of the nitrogen: (i) from free nitrogen; (ii) by the reduction of nitrogen oxides; (iii) from ammonium salts; (iv) by the action of water on the nitrides, amides, etc.; (v) by the decomposition of organic nitrogenous compounds; and (vi) by bacterial action. A review of the German patents on the subject has been made by G. Schuchardt in his *Die technische Gewinnung von Stickstoff, Ammoniak und schwefelsaurem Ammonium* (Stuttgart, 1919).

1. *The formation of ammonia from elemental nitrogen.*—In 1807, H. Davy[1] reported that nitric acid and ammonia are formed during the electrolysis of distilled water with air in soln.—**1.** 3, 6. Lord Rayleigh could not confirm the formation of ammonia, and E. Tiede and A. Schleede failed to obtain a trace of ammonia under varying conditions, and under press. up to 150 atm. On the other hand, F. Fichter and R. Suter said that Lord Rayleigh's failure to verify H. Davy's observations was due to his use of platinum electrodes and a high current density in place of gold electrodes and a low current density. F. Fichter and R. Suter obtained 0·3 mgrm. of ammonia per 100 amp. per min. with nitrogen at 200 atm. press., an electrolyte of one per cent. sulphuric acid, and platinum electrodes of large surface and thickly platinized. The cathode surface quickly loses its efficiency and has to be renewed; its activity cannot be restored by oxidation. No formation of ammonia was observed when a mercury cathode was used. R. Nithack obtained a patent for utilizing the reaction.

C. Zenghelis obtained small yields of ammonia by passing mixtures of nitrogen and hydrogen (1 : 3 vol.) through water or acidulated water with colloidal metals—platinum, palladium, gold, silver, copper, or mercury—in suspension, and at 90°. Small yields were also obtained by passing nitrogen through a mixture of zinc and dil. sulphuric acid at 90°; nascent electrolytic hydrogen; and from a warm soln. of ammonium chloride and potassium nitrate with colloidal platinum as catalyst. H. G. Falk and R. H. McKee found that nitrogen, at 300 lbs. per sq. in. press., and in contact with water at ordinary temp., forms ammonium nitrite $N_2+2H_2O=NH_4NO_2$, as well as traces of nitrate derived from accidental traces of oxygen in the water. An increased yield of nitrite was obtained at 1800 lbs. press., and also with a mixture of alcohol and acetone in place of water as solvent. In vitreous silica or glass vessels, the reaction occurred only in the presence of a catalyst—say a clean piece of iron. J. J. van der Bossche hydrolyzed nitrogen by passing that gas under press. into a soln. which is being electrolyzed between electrodes of ferromanganese. C. B. Jacobs forced nitrogen through a porous cathode and obtained nitric oxide or nitrates during the electrolysis of alkaline soln. K. F. Bonhöffer, and A. L. Marshall and H. S. Taylor doubted if atomic hydrogen can combine with molecular nitrogen to form ammonia—*vide supra*, nitrogen. A. J. Prince showed that the reaction: $N_2+3H_2+2CO+2H_2O=2H.COONH_4$, said by P. R. de Lambilly to occur in the presence of a catalyst, does not occur with platinized asbestos. K. A. Hofmann and E. Will observed the formation of ammonia in the combustion of air in some hydrocarbons. H. Hampel and R. Steinau heat ammonium chloride in the presence of iron filings and the reaction $Fe+2NH_4Cl=FeCl_2+2NH_3+H_2$ occurs; if in the presence of dissociated nitrogen, the nascent hydrogen so formed reacts $3Fe+6NH_3+6HCl+2N=3FeCl_2+6NH_3+2NH_3$, giving 2 mols more ammonia than the ammonia started with. H. Davy noticed that water distilled in contact with a mixture of charcoal and potash furnishes ammonia which he was inclined to attribute to the hydrogenation of the adsorbed nitrogen.

According to C. Morren, A. Geitz, and A. Perrot, when an electric discharge is passed through a mixture of hydrogen and nitrogen, ammonia is formed: E. P. Perman said that if the press. of the mixed gases is increased from one to two atm., the yield of ammonia is doubled. A. Findlay observed the formation of ammonia when the mixed gases are exposed to the brush discharge; and, according to P. and A. Thénard, E. Warburg and W. Rump, C. Chabrier, and W. F. Donkin, a similar result is obtained if the mixed gases be exposed to the silent electric discharge. M. Berthelot obtained a conc. of about 3 per cent. of ammonia by the action of silent discharge on a mixture of hydrogen and nitrogen. E. Hiedemann passed a mixture of hydrogen and nitrogen through an electron tube with an ionization potential a few volts above that of both gases, and obtained a relatively high yield of ammonia; and L. Hamburger found that the conditions which favour the formation of active hydrogen or nitrogen give higher yields of ammonia. C. T. Kwei found that ammonia bands appear at 23 volts, but not at 17 volts. A. R. Olson attributed this to the presence of activated nitrogen at the higher voltage only as observed by T. R. Hogness and E. G. Lunn, H. Sponer, and H. H. Storck and A. R. Olson—*vide supra*, for the action of activated hydrogen or nitrogen.

A. Mirimanoff showed that the most favourable temp. for the formation of ammonia in the silent discharge lies between 450° and 550°; above 650°, no ammonia was formed owing to the increase in *l'instabilité* of ammonia at elevated temp. M. le Blanc and J. H. Davies inquired if the law of mass action applies for the silent electrical discharge. They found that when dry ammonia gas is exposed to the silent discharge at constant temp. and constant current, the rate of decomposition is nearly proportional to the press.; temp. has a comparatively small influence on the rate of decomposition; a rise of 100°, or an increase of the current by one-third, nearly doubles the rate of decomposition. The presence of an excess of hydrogen diminishes the rate of decomposition, whereas an excess of nitrogen increases it. The luminosity of the discharge is much increased by nitrogen, but not by hydrogen. The final condition of equilibrium attained is very little affected by the strength of current used. The ratio $[N_2][H_2]^3/[NH_3]^2$ for different mixtures of hydrogen and nitrogen is not even roughly constant. Hence, the law of mass action does not hold, being apparently valid only when the temp. is so high that the reactions occur under the influence of heat alone. H. B. Moses obtained a sudden chilling of the gases and a correspondingly high yield by forming an arc in a mixture of hydrogen and nitrogen in the vicinity of liquid nitrogen. A. Makowetzky studied the formation of ammonia in the glow discharge with cooled electrodes. A. Günther-Schulze observed no signs of the union of hydrogen and nitrogen in the glow discharge, rather is ammonia thereby completely decomposed.

H. St. C. Deville noted that appreciable quantities of ammonium chloride are produced if a mixture of hydrogen and nitrogen be sparked in the presence of hydrochloric acid; in fact, as H. B. Dixon showed, the conversion of the 3 : 1 mixture of hydrogen and nitrogen is complete if the ammonia be continuously removed from the system by an acid. E. Baur, E. Briner and co-workers, and A. de Hemptinne have also made observations on the synthesis of ammonia by exposing the mixed gases to the electric discharge. On the other hand, J. Priestley, C. L. Berthollet, A. B. Berthollet, W. Henry, and H. Buff and A. W. Hofmann observed that when a succession of electric sparks is passed through dry ammonia, decomposition occurs, and the vol. of gas is doubled. H. St. C. Deville said that there is always a trace of ammonia left after a protracted sparking of the gas. The reaction is, indeed, reversible. R. Pohl passed a silent discharge at 5000–10,000 volts through an ozonizing tube containing ammonia, and found that the presence of traces of moisture inhibits the decomposition of the gas to a considerable extent, and the efficiency also became less when the current was increased; increase of the e.m.f. employed, of the press. of the gas, or of the thickness of the layer traversed had, however, an opposite effect. A. Classen obtained ammonia by subjecting a mixture of hydrogen and nitrogen to the simultaneous action of the silent and spark electric discharges in presence of catalysts—*e.g.* metals and metallic alloys, supported on carriers of an acidic nature. Silica, prepared from water-glass, is well suited for this purpose, as it readily absorbs colloidal metals such as gold, platinum, metals of the platinum and iron groups, as well as their alloys. The efficiency of the catalyst is improved by the presence of a protective colloid—*e.g.* galatose. The mixed gases are passed over the catalyst between two electrodes, one being a good conductor, like copper, and the other a bad conductor, like glass or porcelain. The latter may be immersed in cold water and may concentrically surround the former, the contact material being in the intervening space. The temp. may range from 25° to 90°, according to the conditions, and the press. may be normal, or higher than normal.

E. B. Andersen studied the synthesis of ammonia by the action of a stream of slow-moving electrons on mixtures of the constituent elements. A current was passed between a glowing tungsten filament and two platinum electrodes in the mixed gases. The curves connecting the velocity of formation of ammonia with the applied e.m.f. show maxima at 22, 26, and 33 volts. No appreciable amount of ammonia was produced below an applied e.m.f. of 17·7 volts—the ionizing potential of nitrogen. Hence it is supposed that the first step in the production of ammonia is the ionization of the nitrogen mols. The maximum rate of formation did not correspond with the stochiometrical mixture. H. H. Storch and A. R. Olson found that an increased percentage of nitrogen favours a higher rate of reaction; the formation of ammonia cannot be detected unless an arc is present; and the rate of formation of ammonia depends primarily on the diameter of the hot filament. The variation in the rate of reaction at specific voltages is such as to give abrupt increases with e.m.f. about 4 volts apart. The wave-type of curve observed by E. B. Andersen is attributed to the superposition of a curve showing the effect of the accelerating voltage on the rate of reaction, and a fatigue effect in the mechanism used for absorbing the ammonia.

E. Briner and E. Mettler studied the maximum conc. of ammonia obtained by circulating a mixture of hydrogen and nitrogen through a tube containing a spark-gap; and E. B. Maxted examined the relative efficiency of various types of spark. The sparks from an induction coil were found to be very inefficient, and energetic ammonia formation was found to occur only when the electrodes were sufficiently close to transform the ordinary spark discharge into a small high-tension arc, accompanied by a visible and apparently continuous flame of high temp. With the 3 : 1 mixture of hydrogen and nitrogen flowing at the rate of 40 c.c. per hour, less than 0·1 per cent. of ammonia was contained in the issuing gas with a spark discharge having a 10 mm. spark-gap; with a 5 mm. spark-gap having an incipient flame, 0·25 per cent. of ammonia was formed; and with an arc flame with a spark-gap of 1·5 mm., 0·8 per cent. of ammonia, and when the gap was 0·5 mm., 1·1 per cent. of ammonia was present. E. P. Perman suggested that the formation of ammonia by the electric discharge is due to the formation of ions; but E. Briner and A. Baerfuss said that the discharge dissociates the mols. of nitrogen and hydrogen into atoms, which, diffusing into a zone of lower temp., unite to form ammonia. In support of this hypothesis they stated that by reducing the press. to 100 mm., and also by increasing the nitrogen content of the mixture sparked, the yield of ammonia was augmented. Thus, E. Briner and J. Kahn found:

Initial press. . . .	696·15	463·15	251·2	149·95	100·5 mm.
Final press. . . .	685·35	458·35	248·7	148·90	97·7 mm.
Ammonia	1·55	1·08	1·0	0·7	2·35 vol.

G. Falckenberg studied the formation and decomposition of ammonia in the silent electrical discharge.

W. R. Grove found that ammonia is decomposed by an electrically heated wire, and J. Plücker showed that the effect is merely thermal, not electrical. E. Warburg and E. Regener studied the effect of rays of short wave-length; and H. Coehn and G. Pringent, H. S. Taylor, and D. Berthelot and H. Gaudechon, the effect of ultra-violet light. In neither case does the effect appear to favour the synthesis of ammonia from its elements—*vide infra*. C. Montemartini observed the formation of ammonia from its elements in the corona discharge. H. S. Hirst detected traces of ammonia and hydrazine in the products of the reaction between nitrogen and hydrogen when exposed in silica tubes to ultra-violet light. A. C. G. Mitchell and R. G. Dickinson found that the decomposition of ammonia was effected by light of wave-length 2537A, and is sensitized by the presence of mercury vapour. For the synthesis of ammonia by the action of atomic hydrogen on nitrogen, *vide supra*, nitrogen.

F. Kuhlmann observed no sign of the formation of ammonia when a mixture of one vol. of nitrogen with 3 vols. of hydrogen is passed through a red-hot tube, even in the presence of spongy platinum. G. S. Johnson's observation to the contrary was shown by L. T. Wright, and H. B. Baker to be mal-inference due to the use of an unsuspected impurity in the nitrogen employed—namely, nitric oxide. M. Berthelot heated the 1 : 3 mixture, under diminished press., in a quartz tube at 1300°, for an hour, but observed no sign of the formation of ammonia, even when the tube was rapidly cooled. E. B. Maxted, and H. Tominaga observed the formation of ammonia and nitric oxide when a mixture of hydrogen and nitrogen is heated under 30 atm. press. by the oxyhydrogen flame. The water produced is probably dissociated, forming nitric oxide which is reduced by hydrogen to ammonia—*vide* the oxidation of nitrogen. M. Guichard, A. T. Larson and co-workers, R. S. Tour, and W. W. Scott studied the suitability of various catalysts. M. Guichard found that the addition of magnesia or nickel, tungsten, and molybdenum, and a combination of two of these metals, ensures greater catalytic efficiency. Iron-molybdenum was proved to be the most resistant and to give the highest ammonia concentration—more than 4 per cent. Iron alone gave less than 1 per cent., molybdenum less than 1·5 per cent., nickel 3 per cent., and cobalt 3 per cent. The best method of preparation is by precipitation of ferric nitrate with ammonium molybdate, followed by ignition, and subsequent reduction. With perfectly dry gases, uranium is a suitable catalyst, but its combinations with cobalt or molybdenum are of inferior value as catalysts. Uranium-nickel gives poor results, and uranium-tungsten is practically inert. R. N. Pease and H. S. Taylor found that a mixture of iron and molybdenum is a better catalyst for the ammonia reaction than is the case with either alone. H. Harter and J. M. Meyer used platinized pumice soaked in ammonium tungstate as catalyst. The Nitrogen Corporation obtained a catalyst by soaking pumice-stone in barium and calcium ferrocyanides and subsequently drying and igniting the mass ; L. Duparc and C. Urfer used the mixture obtained by heating aluminium or magnesium with an oxide of lithium, calcium, barium, strontium, beryllium, titanium, vanadium, molybdenum, or uranium. According to S. L. Tingley, ammonia is produced by passing nitrogen and hydrogen under press. through a liquid composition of mercury and osmium at a temp. below the b.p. of mercury, the press. being less than 200 atm. R. W. G. Wyckoff and E. D. Crittenden studied the X-radiograms of some ammonia catalysts. E. Baur did not induce hydrogen and nitrogen to form any ammonia by passing the mixed gases over platinum-black at 100°, or over chromium or molybdenum nitrides, or by leaving the two gases over platinized-platinum foil in the presence of hydrochloric acid. F. de la Roche, and J. B. Biot confined a mixture of hydrogen and nitrogen by mercury, having a stratum of dil. nitric acid on its surface, and sunk the vessel 540 metres in the sea. This would be eq. to a press. of about 50 atm., but no ammonia was formed. F. Varrentrapp and H. Will stated that ammonia is formed when the mixed gases are passed through a tube containing soda-lime, and if lampblack, or a mixture of carbonized potassium tartrate and lime be used, the synthesis occurs at a low temp. H. Fleck said that when a mixture of nitrogen, steam, and carbon monoxide is passed over calcium hydroxide at a dull red-heat, 5 mgrms. of ammonia are produced per 500 litres of air. R. Weinmann denied this. O. Loew, and F. Wöhler found that ammonia (and a trace of nitrate or nitrite) is formed when a mixture of nitrogen and hydrogen is passed over platinum-black moistened with a little potash-lye ; and O. Loew and K. Aso found that if the platinum-black is moistened with water, ammonia is slowly formed. L. Brunel and P. Woog did not synthesize ammonia by passing the constituent gases over a mixture of thorium and cerium oxides, palladinized-pumice, quicklime, soda-lime, calcium chloride, calcium molybdate, barium or strontium oxide, manganese dioxide, aluminium phosphate, or magnesium phosphate at 15°–350°. There is a trace of ammonia formed with nickel sesquioxide as catalyst at 180°–200° ; and with air and hydrogen, over nickel sesquioxide at 200°–240°, small quantities of ammonia are continuously formed. P. Neogi and B. B. Adhicary observed no ammonia is produced when a mixture of hydrogen and nitrogen is passed over reduced iron at a temp. varying from dull to bright redness. A negative result was also obtained with iron or nickel wire, electrolytic nickel, reduced nickel, or ferric oxide. W. A. Noyes, and H. C. Woltereck obtained ammonia by passing the mixed gases over thin layers of iron spread on asbestos at 550°; iron oxide gave a better result, and similar results were obtained with the oxides of nickel, cobalt, copper, cadmium, silver, lead, bismuth, and chromium. The reaction is continuous if air be used in place of nitrogen. 300°–350° is the most favourable temp. with iron oxide. The reaction also takes place with charcoal, coke, or peat as catalytic agent.

E. Royer and E. Jacquémin made ammonia by passing a mixture of steam and hydrogen over white-hot carbon; S. L. Tingley passed steam and nitrogen over heated calcium carbide; and L. I. de Nagy Ilosva, and M. Berthelot obtained ammonium nitrite and nitrate during the combustion of a mixture of nitrogen, oxygen, and hydrogen in excess; and also during the combustion of organic substances in air. H. W. Blackburn and W. Thomas passed nitrogen and steam, at about 2 atm. press., over a heated catalyst—*e.g.* iron at 500°: iron and nickel at 1000°; nickel oxide at 400°; ferrous oxide at 400°; or charcoal at about 800°. P. R. de Lambilly found that if a mixture of nitrogen, hydrogen, steam, and carbon monoxide is passed over pumice-stone, bone-black, or spongy platinum, ammonium formate is produced: $N_2+3H_2+2CO+2H_2O=2H.COONH_4$; while if carbon dioxide be employed, ammonium hydrocarbonate results: $N_2+3H_2+2CO_2+2H_2O=2NH_4HCO_3$. In applying these reactions on a large scale, the gases can be obtained by the alternate action of air and steam on white-hot coke, and, according to the product desired, carbon monoxide or dioxide is removed from the gas mixture to be treated. Spongy platinum was found to be the best catalyst, and a temp. of 80°–130° most suitable for the formate, and 40°–60° for the hydrocarbonate. J. Schlutius exposed a mixture of steam and producer gas (14 per cent. H_2; 43, N_2; 39, CO; and 4, CO_2) to the action of a silent discharge in the presence of platinum, and obtained ammonium formate above 80°; and ammonia, below that temp.

J. Priestley found that ammonia is decomposed into its elements when passed through a red-hot glass tube; A. B. Berthollet obtained a similar result using a porcelain tube; and H. St. C. Deville and L. Troost obtained a 75·8 per cent. decomposition at 1100°. J. M. Crafts obtained a 30 per cent. decomposition after 7–8 minutes' heating. J. Bouis, and L. J. Thénard found the decomposition is more marked if the tube be packed with fragments of porcelain or pumice-stone. A. H. White and W. Melville say that the decomposition begins at about 450°. H. C. Woltereck said that the first signs of dissociation with dry ammonia occur at 620°, and that if traces of moisture or organic matter be present, dissociation occurs at a lower temp.; in the presence of heated iron gauze, decomposition commenced at 320°; and with ferric oxide, no decomposition occurred below 420°. M. Berthelot found that the decomposition is slow at 600°, and faster at 800°. The decomposition is complete at 1300°. W. Ramsay and S. Young said that the reaction begins at 500°, and is almost complete at 780°; and the degree of decomposition attained is determined by the velocity at which the gas is passed through the hot tube. According to A. T. Larson and co-workers, when ammonia gas is decomposed into its elements by passing it over hot steel wool, at first the decomposition is slow, but later as the steel wool becomes sufficiently activated the greater portion of the gas is decomposed on its surface, and the free ammonia in the exit gases falls to about 0·01 per cent. M. Bonet y Bonfill believed that the presence of lime favours the decomposition, but J. Bouis could not confirm this. K. von Than showed that indifferent gases hinder the decomposition so much that with ammonia alone at a bright red-heat, 14·08 per cent. was decomposed, whereas in the presence of steam, 0·35 per cent. was decomposed, and in the presence of mercury vapour, 0·68 per cent. A. H. White and W. Melville observed that the rate of decomposition is increased a little in the presence of carbon monoxide or water-vapour ; and that a little cyanogen is formed in the case of carbon monoxide—more with dry than with moist gases. L. J. Thénard, and A. B. Berthollet found that the decomposition occurs more readily in the presence of platinum, gold, silver, copper, or iron. K. von Than observed no reaction in the presence of mercury at 350°. E. P. Perman and co-workers stated that ammonia can be synthesized by heating the mixed elemental gases in the presence of metals—*e.g.* iron, copper, nickel, zinc, cobalt, palladium, aluminium, and magnesium—but metals which readily form nitrides—*e.g.* magnesium—are not more active than other metals, and hence nitrides are not an intermediate stage in the formation of ammonia. The action of various metals was studied by E. P. Perman and C. A. S. Atkinson, M. Berthelot, F. Haber and co-workers, etc. As L. J. Thénard has shown, the metals undergo no noticeable change in weight, but copper and iron become brittle while gold and platinum remain unchanged. The decomposition of ammonia in the presence of platinum was studied by F. H. Constable. E. C. C. Baly and H. M. Duncan observed what they considered to be two different mol. phases of ammonia exist possessing different energy contents and reactivities, that of lower energy content being identical with completely dry ammonia. They found that the decomposition of ammonia by means of a heated, activated platinum wire gives constant values for the same amount of energy with an *active* form of the gas derived either by slow evaporation from a cylinder of compressed gas, or by gently heating the concentrated aq. soln., the gas being dried by quicklime, or by evaporating isothermally at the b.p. the gas obtained by either of these methods. A second *inactive* type, obtained by rapid evaporation of the liquefied gas, gives much smaller decomposition values under the same conditions. On standing in contact with the liquefied gas, or by heating to 200° with a platinum wire, this type slowly becomes active. The ratio of the decomposition values obtained by a first and second exposure of the gas to the heated wire differs markedly in the two forms. The addition of water vapour increases the reactivity of ammonia proportionally to the amount of water present, an increase which is lost on drying with quicklime. According to E. P. Perman, ammonia is formed by exploding the constituent elements with oxygen. The gas cannot be decomposed by heat, and therefore the reaction is not reversible ; on the contrary, M. Berthelot, and many others, have studied the reversibility of the reaction.

The equilibrium conditions of the reversible reaction: $N_2+3H_2 \rightleftharpoons 2NH_3$, or $\frac{1}{2}N_2+1\frac{1}{2}H_2 \rightleftharpoons NH_3$, were established by F. Haber and G. van Oordt. If the bracketed symbols denote the partial press. of the respective gases, $[NH_3]^2=K_p[N_2][H_2]^3$, where K_p denotes the equilibrium constant at constant press., the conc. of the amount present depends on the press. and on the temp. In studying the reaction, the equilibrium is only slowly attained at low temp., consequently F. Haber and G. van Oordt employed iron and nickel as catalytic agents ; and F. Haber and R. le Rossignol, iron, manganese, nickel, and chromium. The results showed that with 1 : 3, gas mixture, at atm. press., for equilibrium :

K_p	700°	750°	800°	850°	930°	1000°
	c. 0·00068	0·000468	0·000334	0·000279	0·000200	0·000148
NH_3	c. 0·0221	0·0152	0·0109	0·0091	0·0065	0·0048 per cent. vol.

It follows from the equilibrium equation that *the maximum conc. of ammonia at equilibrium is obtained when the hydrogen and nitrogen are present in the proportions three to one by volume.* The reaction is exothermal at ordinary temp.—being 11·89 Cals. per mol ammonia—so that the effect of raising the *temperature* will be to decrease the conc. of the ammonia. To keep the conc. of the ammonia high, the temp. of the reaction should be low ; but the reaction is then too slow for industrial work unless a suitable catalytic agent can be found. W. Nernst, and F. Jost obtained rather lower results, due, according to F. Haber and R. le Rossignol, to the mixtures referred to by W. Nernst, and F. Jost not being in equilibrium. E. B. Maxted found that mixtures of hydrogen and nitrogen furnished 0 and

3 per cent. of ammonia, when the gases are in contact with an arc at 3000°, Fig. 21. E. Briner and co-workers, E. Maurer, S. Dushman, and R. O. E. Davis and L. B. Olmstead have studied this subject. The equation for the influence of temp. on the equilibrium conc. of ammonia, deduced from these observations, is $\log_{10} K_p = 2098T^{-1} - 2\cdot5088 \log_{10} T + 0\cdot0001006T + 0\cdot0_6186T^2 + 2\cdot1$; or, approximately, $\log_{10} K_p = 2888T - 6\cdot134$. R. S. Tour has made a study of the graphs of this equation.

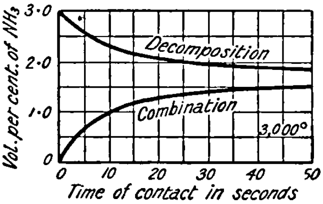

FIG. 21.—The Effect of Time on the Reaction at 3000°.

G. E. Foxwell studied the thermal decomposition of ammonia diluted with coal-gas in silica tubes packed with porous materials like coke or firebrick, and at temp. between 520° and 850°. When an excess of solid surface is present the decomposition is bimolecular. The velocity of decomposition, when the tube is filled with coke, increases slowly with increasing temp., the temp. coeff. being 1·136. The value of the velocity constant, k, may be expressed by the formula $k_2 = k_1 eA(1/T_1 - 1/T_2)$, where A is 13,300. For tubes with a radius less than 0·5 cm., k varies inversely as the square of the radius, but it is probable that for wider tubes k varies inversely as the radius. When gases containing ammonia are passed through porous material, the amount of decomposition in unit time varies directly as the square of the radius of the pores; hence it is the size of the pores rather than the total porosity that is of importance. Silica bricks have considerably less decomposing effect than siliceous (80 per cent. SiO_2) bricks, whilst the presence of iron is very deleterious. The composition of the ash of the coke affects the rate of decomposition. Rutile and orthoclase have very little, if any, action; iron pyrites is converted into ferrous sulphide during carbonization, and this increases the velocity of decomposition to some extent. Iron oxide, which is converted into metallic iron, enormously increases the rate of decomposition, and the same is true, although to a less extent, of lime. The value of k for coke is found to be 0·00200 at 755°. G. F. Uhde obtained a catalyst by heating a mixture of aluminium chloride and potassium ferrocyanide.

The above equation shows that at a constant pressure the concentration of the ammonia decreases with a rise of temperature, which allows for the variation of the thermal value of the reaction with temp. At 27°, the conc. of the ammonia at equilibrium will approach 96·32 per cent., so that a good yield of ammonia could be obtained, by direct synthesis from its elements, if a suitable stimulant could be found. For J. Lipsky's observations on the catalytic effects of cerium hydride and nitride, *vide supra,* cerium nitride. Even with the best catalyst known it is difficult to obtain satisfactory results below 500°, and it is not necessary to work over 700° since equilibrium is attained quickly enough just below this temp. E. B. Maxted has said: "It must be borne in mind that, as the synthesis of ammonia is usually carried out, the percentage of ammonia formed during the passage of the gas through the catalyst never approaches the equilibrium value for the temp. and press. used, and thus, within limits, of course, reaction velocity plays an even more important *rôle* in the determination of the amount of ammonia formed during the time of contact than the absolute value of the equilibrium ammonia percentage. If, on the other hand, the temp. employed be so high that the desired percentage of ammonia unduly approaches the equilibrium percentage, the increase in the reaction velocity due to increased temp. will no longer compensate for the decreased equilibrium ammonia content." The proportion of ammonia in the mixture of gases in equilibrium at different temp., computed by E. B. Maxted, is plotted in Fig. 22. An

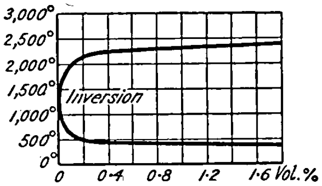

FIG. 22.—Effect of Temperature on the Equilibrium Concentration of Ammonia.

inversion occurs at about 1200°, so that above this temp., the yield of ammonia should increase with rise of temp. This was confirmed experimentally by E. B. Maxted; and A. Fowler and C. C. L. Gregory's observations of ammonia in the solar spectrum lends support to these results. E. Briner pointed out that when working at very high temp., the equilibrium formula applicable at lower temp. may have to be modified because of the dissociation of, say, hydrogen and nitrogen into atoms, and the extra production of, say, ammonia, may be due to the greater kinetic energy of the free atoms of hydrogen and nitrogen. To find the effect of *pressure*, let p denote the total press. of the gas, and C the fraction of the total vol. which each gas forms at equilibrium, it follows that $[NH_3]=pC_{NH_3}$; $[N_2]=pC_{N_2}$; and $[H_2]=pC_{H_2}$, substituting these values in the equilibrium equation, $C_{NH_3}/C^{\frac{1}{2}}{}_{N_2}C^{\frac{3}{2}}{}_{H_2}=pK_p$. When the conc. of the ammonia is small, the product $C^{\frac{1}{2}}{}_{N_2}C^{\frac{3}{2}}{}_{H_2}$ will be almost constant. Hence, the conc. of the ammonia at equilibrium will be nearly proportional to the total press. Hence, raising the press. 30 atm. should increase the conc. of the ammonia 30-fold. With the 3 : 1 gas mixture, *the concentration of the ammonia at a given temperature increases with rise of pressure.* The effect of pressure is indicated in Table XII, by F. Haber and R. le Rossignol.

TABLE XII.—EFFECT OF PRESSURE AND TEMPERATURE ON THE EQUILIBRIUM CONCENTRATION OF AMMONIA.

Temp.	Pressures.				
	1 atm.	30 atm.	100 atm.	200 atm.	1000 atm.
200°	15·30	67·6	80·6	85·8	—
300°	2·18	31·8	52·1	62·8	—
400°	0·48	10·7	25·10	36·3	—
500°	0·129	3·62	10·40	17·6	—
550°	—	—	7·00	12·2	40 (536°)
600°	0·049	1·43	4·47	8·25	30 (607°)
650°	—	—	3·00	5·8	20 (672°)
700°	0·0223	0·66	2·14	4·11	—
750°	0·0159	—	1·54	2·99	14 (740°)
800°	0·0117	0·35	1·15	2·24	—
850°	0·0089	—	0·874	1·68	—
900°	0·0069	0·21	0·68	1·34	—
950°	0·0055	—	0·542	1·07	—
1000°	0·0044	0·13	0·44	0·87	—

The last column is due to G. Claude. Some results at other press. were obtained by E. Briner and co-workers, and M. Guichard. W. Moldenhauer found the yields with increased press. agree well with the calculated values at 740° and 1000 atm. press. At lower temp., the discrepancies increase as the temp. falls and the press. rises. They are attributed to differences in the compressibilities of the different gases. G. Claude's process was described by J. H. West, and H. V. Tartar and M. F. Perkins; and R. Schönfelder concluded from an examination of the different industrial processes that G. Claude's process is the most efficient. M. Lheure, and F. Meyer described this process. S. W. Saunders obtained not so good results with $\log K_p=4790T^{-1}-5{\cdot}38\log T+0{\cdot}0001225T+0{\cdot}0_61569T^2-0{\cdot}8$, where $K_p=p^2{}_{NH_3}/p^3{}_{H_2}p_{N_2}$, as with $\log K_p=4686T^{-1}-3{\cdot}5\log T+0{\cdot}0001225T+0{\cdot}0_61569T^2-0{\cdot}8$. A. T. Larson and co-workers found that percentages of ammonia in the equilibrium conditions of $\frac{1}{2}N_2+1\frac{1}{2}H_2 \rightleftharpoons NH_3$—pressures in atm.—are:

Press.	10	30	50	100	300	600	1000
200° .	50·66	67·56	74·38	81·54	89·94	95·37	98·29
300° .	14·73	30·25	39·41	52·04	70·96	84·21	92·55
400° .	3·85	10·15	15·27	25·12	47·00	65·20	79·82
500° .	1·21	3·49	5·56	10·61	26·44	42·15	57·47
600° .	0·49	1·89	2·25	4·52	13·77	23·10	31·43
700° .	0·23	0·68	1·05	2·18	7·28	12·60	12·87

The values of the equilibrium constant are represented by $\log K_p=aT^{-1}+b\log T+cT+dT^2+I$, where $p_{\mathrm{NH}_3}=K_pP_{\mathrm{N}_2}\tfrac{1}{2}p_{\mathrm{H}_2}$, and

Atm. press.	*a*	*b*	*c*	*d*	*I*

300	2074·8	−2·4943	$-1{\cdot}256\times10^{-4}$	$1{\cdot}856\times10^{-7}$	2·206
600	2074·8	−2·4943	$-1{\cdot}0856\times10^{-3}$	$1{\cdot}856\times10^{-7}$	3·059
1000	2074·8	−2·4943	$-2{\cdot}6833\times10^{\ 3}$	$1{\cdot}856\times10^{-7}$	4·473

L. S. Gillespie represented the equilibrium constant, K_p, for temp. between 325° and 500°, and from 100 atm. to the lowest press., by $\log K_p=(2679{\cdot}35+1{\cdot}1184_p)T^{-1}-(5{\cdot}8833+0{\cdot}001232p)$; and for higher press. by $\log K_p=(2172{\cdot}26+1{\cdot}99082p)T^{-1}$. W. G. Shilling gave $\log K_p=-2068T^{-1}-2{\cdot}9278\log T+0{\cdot}0_32756T+0{\cdot}0_7513T^2+3{\cdot}1490$. This subject was studied by F. G. Keyes; and A. F. Benton investigated the kinetics of reactions in flow systems. R. E. Burk measured the rate of decomposition of ammonia by a heated molybdenum wire.

M. Bodenstein and F. Kranendieck showed that the decomposition of ammonia in quartz vessels is a surface reaction. It is inferred that the decomposition of the ammonia takes place in the pores of the quartz glass, and that the velocity of the change is determined by the rate at which the ammonia diffuses into the pores. The actual decomposition probably occurs very rapidly, but the speed of the chemical reaction is determined to some extent by the velocity with which the products of decomposition escape from the pores in the quartz into the space occupied by the gas. C. N. Hinshelwood and R. E. Burk found that the thermal decomposition of ammonia in quartz vessels, and on the surfaces of heated platinum and tungsten wires, is in equilibrium with almost complete decomposition. The reaction on the silica surface is of the first order with respect to ammonia, and it is strongly retarded by hydrogen. They found that the nature of the silica surface has a marked effect on the temp. of the reaction. They observed that in suitable silica vessels (1) the added hydrogen may have just as large a retarding effect as hydrogen formed *in situ* by the reaction, (2) the temp. coefficient may be very high, and (3) the retarding influence of the products may be constant over a range of 200°. The reaction on a heated platinum wire is of the first order as regards ammonia, and is retarded by hydrogen, but differently from the retardation in the case of silica, the equation being $d[\mathrm{NH}_3]dt=k[\mathrm{NH}_3]^n/[\mathrm{H}_2]$, where n is approximately equal to 1. Nitrogen has practically no effect on this reaction, which corresponds with a heat of activation of 140,000 cals. The reaction on a heated tungsten wire is of zero order with respect to ammonia, and is uninfluenced by the products of reaction It is much more rapid than with platinum, but the temp. coeff. is smaller and corresponds with a heat of activation of 38,700 cals.

In 1901, H. le Chatelier, reasoning from the law of mass action, showed that ammonia could be synthesized by heating above dull redness a mixture of hydrogen and nitrogen under press. in the presence or absence of spongy platinum, or finely divided iron. The industrial applications of the facts were covered by a patent which was allowed to lapse. G. Claude has devised a plant for increasing the yield of ammonia by working at a very high press., say 900–1000 atm. While the gas passing from the catalyst has ammonia corresponding, at 200 atm. press., with a 13 per cent. yield, at 1000 atm., there is a 40 per cent. yield. F. W. de Jahn claimed to have improved F. Haber's process by working at 520°–540° under a press. of 80–90 atm. over a catalyst formed by igniting a salt of cobalt, nickel, manganese, titanium, cerium, boron, uranium, or silicon upon a carrier of pumice-stone, and, after reduction in hydrogen, heating the product in contact with metallic sodium and anhydrous ammonia at 300°. With the catalyst prepared from a nickel salt, 4·5 per cent. by vol. of ammonia was obtained.

Although many important details are judiciously reserved as trade secrets, the general features of **F. Haber's ammonia process** appear to involve the preparation of nitrogen of a high degree of purity from liquid air. The reaction chamber, illustrated diagrammatically in Fig. 23, consists of a thin steel or wrought-iron tube, *A*, inside of which is a glass or fused quartz tube, *B*, narrowed towards the lower end so as to retain the catalyst, *C*, between asbestos plugs. The tube *A* is heated to 500°–600° by means of a coil of resistance wire *W* wound over the iron tube wrapped in a sheet of asbestos. The heating may also be done by internal combustion. The 3 : 1 gas mixture enters the reaction chamber, *viâ D*, and leaves the chamber at the bottom, *viâ E*. The reaction chamber is enclosed in a stronger steel tube, *F*, in which a high press. is maintained so as to prevent the thin steel tube *A* bursting under its internal press. over 150 atm. The mixed gases are forced through the chamber so that an ammonia conc. of about 8 per cent. is maintained. On leaving the furnace at *E*, the gases may be passed through a refrigerating system to liquefy the ammonia, or passed, while under press., through water or dil. acid to absorb the ammonia. In either case, the unconverted hydrogen and nitrogen are returned to the reaction chamber—*cf.* Fig. 24. Modifications were devised by L. Casale, G. Fauser, etc. Various plants have been described by J. R. Partington, R. S. Tour, A. Miolati, J. A. Harker, C. S. Imison and W. Russell, C. H. Jones, M. Lheure, M. Patart, A. Zambianchi, J. S. Negru and S. D. Kirkpatrick, F. A. Ernst and co-workers, and H. Schmidt.

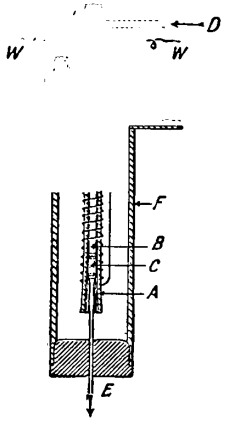

Fig. 23.—Diagrammatic Representation of the Reaction Chamber of F. Haber's Ammonia Process.

The most effective catalyst for accelerating the velocity of formation of ammonia was found to be osmium; but it is too scarce for commercial work. Next came uranium, which, in the form of carbide, crumbles to a fine powder under the conditions, and then at 500° has a high catalytic activity provided water be absent. Iron, tungsten, molybdenum, molybdic acid, ammonium molybdate, cerium, and manganese were found to be good catalysts. The catalytic activity of tungsten depends on the way it has been prepared. Platinum was found to be a poor catalyst. E. Decarrière studied palladium and platinum as catalysts; A. T. Larson and C. N. Richardson, magnetite; A. T. Otto and Sons used a metal of the iron group along with a metal oxide not easily reduced and a third substance for producing a glaze; C. Ellis, cobalt vanadate; H. Harter, a metal of the iron-group with an oxide of magnesium, titanium, thorium, vanadium, molybdenum, or tungsten; and C. H. Kunsman, a mixture of iron, aluminium, and an alkali-metal—cæsium. H. A. Bernthsen reported that certain foreign substances, *promoters*, increased the activity of the catalyst. Thus, the oxides and hydroxides of the alkalies and the alkaline earths augment the efficiency of some catalysts. A minute proportion of the promoter often suffices. A mixture of iron and potash is said to be particularly active. E. Collett used ferrites of calcium, barium, magnesium, and manganese. A comparison of uranium carbide, and the iron-potash mixture, by

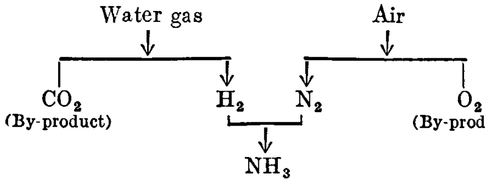

Fig. 24.—Flow Sheet of F. Haber's Ammonia Process.

F. Haber and H. C. Greenwood, and E. B. Maxted, is shown in Fig. 25. K. Inaba used iron oxide mixed with bismuth and thorium oxides as promoters; and L. H. Greathouse, a mixture of iron and manganese oxides with just enough aluminium powder to initiate the thermite reaction and fuse all the oxides. A. T. Larson used two promoters and found the joint action to be greater than either alone. Thus, an iron catalyst with alumina gave a gas with 8 per cent. of ammonia, and one with potassium oxide a gas with 5 per cent. of ammonia, whereas a mixture of the two promoters gave a gas with 14 per cent. of ammonia. A. T. Larson and A. P. Brooks found that nickel, and cobalt are inactive between 450° and 550°; molybdenum, and tungsten are most active at 550°; and iron, and a mixture of iron and molybdenum, at 450°. The action of iron is promoted by the oxides of aluminium, silicon, zirconium, thallium, cerium, and boron, but not so much so by the oxides of lanthanum, beryllium, magnesium, the alkaline earths, and alkalies. Mixtures of potassium hydroxide with alumina, silica or zirconia produced very active catalysts in conjunction with iron. J. A. Almquist and E. D. Crittenden found that the activity of iron depends on the state of oxidation of the fused oxide from which it is obtained by reduction—the magnetic oxide gave the best results. Potassium hydroxide has a marked promotor action if used in conjunction with difficultly reducible oxides like those of manganese, silicon, tungsten and aluminium, while potassium hydroxide alone lowers the activity of iron—so do the oxides of nickel and cobalt.

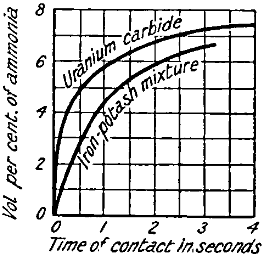

FIG. 25.—Relative Catalytic Activity of Uranium Carbide, and the Iron-potash.

A. T. Larson observed that sulphur, selenium, tellurium, phosphorus, arsenic, boron, bismuth, lead, tin, and many organic compounds act as poisons in diminishing or inhibiting the activity of the catalysts. Iron with one per cent. of sulphur is useless. One part of sulphur per million of the gas mixture is injurious. J. A. Almquist and C. A. Black found that the presence of oxygen or water-vapour reduces the activity of iron as a catalyst. E. B. Ludlam observed that the presence of hydrogen chloride slightly favours the formation of ammonia, but not so much as might be anticipated from the law of mass-action. A. Schmidt studied the action of water vapour and of hydrogen chloride. J. A. Almquist and C. A. Black found that with iron catalysts at 444° the activity is lowered by oxygen, and this the more the greater the conc. of the oxygen. Water-vapour acts similarly. E. Eloed and W. Banholzer studied the effect of varying the rate of the flow of the gas in the decomposition of ammonia by passage over a red-hot catalyst—iron, copper, or alumina. Hydrogen retards the velocity of decomposition.

C. H. Kunsman studied the thermionic properties of some catalysts; and G. B. Kistiakowsky, activation of nitrogen by catalysts by measuring its critical potentials when it is adsorbed on metal surfaces. He found two critical potentials—iron, 10·8 and 13·0 volts; nickel, 10·8 and 13·1 volts; copper, 10·8 and 13·3 volts; and platinum, 11·0 and 13·3 volts. The ionization at about 11 volts is attributed to the nitrogen atom or to a kind of excited or activated nitrogen molecule—probably the former. In agreement with the observations of L. B. Olmstead, A. W. Gauger, and J. H. Wolfenden, the ionization at 13 volts probably belongs to adsorbed hydrogen, and C. F. Fryling inferred from his observation that hydrogen on nickel is dissociated into ions. There is a critical potential at 17 volts which is attributed to molecular nitrogen, and one at 16 volts attributed to molecular hydrogen. W. A. Dew and H. S. Taylor observed a possible relation between the heat of absorption of ammonia and catalytic activity with the reaction: $2NH_3=N_2+3H_2$.

General discussions on the ammonia process for the fixation of nitrogen have been made by E. B. Maxted, *Ammonia and the Nitrides*, London, 1921; J. Knox, *The Fixation* *of Atmospheric Nitrogen*, London, 1914; H. J. M. Creighton, *How the Nitrogen Problem has been Solved*, Philadelphia, 1919; *Journ. Franklin Inst.*, 187. 377, 599, 705, 1919; F. Pope, *Refrigerating Eng.*, 12. 209, 1926; G. Fauser, *Atti Congr. Naz. Chim. Ind.*, 93, 1924; F. G. Cottrell, *Chem. Age*, 11. 282, 310, 342, 1924; F. A. Ernst, *Trans. Amer. Inst, Chem. Eng.*, , , 1926; P. Firmin, *L'Ind. Chim.*, 9. 147, 1922; J. R. Partington, in T. E. Thorpe, *Dictionary of Applied Chemistry*, London, 4. 568, 1922; P. H. S. Kempton, *Industrial Nitrogen*, London, 1922; G. Schuchardt, *Die technische Gewinnung von Stickstoff, Ammoniak und schwefelsauren Ammonium*, Stuttgart, 1919; B. Waeser, *Die Luftstickstoffindustrie*, Leipzig, 1922.

E. Baur made a gas-cell with hydrogen and nitrogen confined over a soln. of ammonia in a sat. soln. of ammonium nitrate, and obtained a current with an e.m.f. of about 0·6 volt. The hydrogen and nitrogen disappeared from the positive and negative poles in the proportion of 3 : 1 by vol. A constant e.m.f. was obtained at —10°. If a 25 per cent. soln. of ammonia in *N*-KCl was employed, no constant e.m.f. was observed. According to C. Bourdclain,[2] ammonia is formed during the rusting of iron in air; and S. Cloez observed that ammonia is formed by the slow oxidation of iron, zinc, or lead, in moist air. This observation was confirmed by W. Austin, A. Chevallier, F. Kuhlmann, and J. J. Berzelius, although M. Hall could not verify the result. A. C. Becquerel also noted that when turmeric paper is laid on plates of zinc, lead, or iron, moistened with water, the paper is reddened in places after 15 minutes' exposure; when warmed, the colour disappears. If the wetted plates are covered with white paper, and the latter after some time is introduced into a glass tube, ammonia is disengaged when heat is applied. C. P. Collard de Martigny observed that moist zinc-filings in a bottle exposed to air also produced ammonia. C. Sprengel obtained a similar result with moist smithy scales; and M. Sarzeau, with ferrous hydroxide. According to M. Faraday, large quantities of ammonia are disengaged when the hydroxide of potassium, sodium, barium, or calcium is heated with potassium, arsenic, zinc, lead, tin, or iron; smaller quantities are obtained with copper; and none at all with gold or noble metals. The ammonia is produced not only when the mixture is heated in air, but also when heated in hydrogen. G. Bischof explained the formation of ammonia in an atmosphere of hydrogen by assuming that the gas employed was not free from atm. air, and consequently of nitrogen; and J. Reiset showed that the sulphuric acid employed in the preparation of hydrogen contains nitrogen oxides. The ammonia may be formed by the action of nascent hydrogen, $Fe+3H_2O=Fe(OH)_3+3H$, either on the nitrogen of the air: $2Fe+6H_2O+N_2=2Fe(OH)_3+2NH_3$, or on the nitrates commonly present in air: $8Fe+15H_2O+3HNO_3=8Fe(OH)_3+3NH_3$—*vide infra*. The formation of ammonia in this way was doubted by H. Will. W. Thomas obtained ammonia by passing a mixture of nitrogen and steam (1 : 4) over carbon, or other catalyst, at 800°. According to E. R. Wötzcl, ammonia is formed from ionized nitrogen and nascent hydrogen obtained by passing nitrogen or flue gases through a hot bed of carbon, and then through a discharge of high-tension electricity immediately below which a jet of steam or atomized water is introduced in the same direction as the flow of the nitrogen. The gases are then cooled to condense the ammonia.

S. Peacock obtained ammonia by passing nitrogen over aluminium hydride at 400° or over. W. Austin found that a wet mixture of iron-filings and sulphur produces ammonia when exposed to air; C. F. Hollunder obtained ammonia by dropping water on a warm mixture obtained by fusing potassium polysulphide and iron-filings in air; and C. Leroy, from the liquid obtained by boiling grey antimony sulphide with a soln. of sodium carbonate in air. C. Herzog showed that ammonium sulphate is formed when water sat. with hydrogen sulphide is kept for a year in a bottle containing air. According to G. J. Mulder, ammonia is formed when a mixture of air and hydrogen sulphide is passed over pumice-stone or wood-charcoal at 30°–40°. T. Fleitmann could not verify these observations. C. Decharme said that air conducted over moist soil at 10°–52° forms ammonia, but A. Muntz and H. Condon said that the ammonia is formed in the soil by definite bacteria acting on the nitrogenous matters there present. H. Davy proved that in the electrolysis of water, with air in soln., ammonium nitrites or nitrates are formed—*vide supra;* G. Meissner obtained the same products by passing ozonized air through water; and C. F. Schönbein, by the evaporation of water in air, and the condensation of water-vapour from air. The hydrogen which escapes from some varieties of steel when fractured—*vide supra*—was supposed by M. Barré, and P. Regnard to form ammonia in contact with atm. nitrogen.

2. *The formation of ammonia by the reduction of oxygen-nitrogen compounds.*—Most gaseous nitrogen-oxygen compounds form ammonia if they are mixed with hydrogen and passed over warm platinum-sponge, platinized asbestos, or platinum-black. Thus, F. Kuhlmann[3] found that warm, not cold platinum-sponge or platinum-black converts nitrous oxide into ammonia; and M. Faraday, S. Cooke, F. Kuhlmann, P. Hare, and P. L. Dulong and L. J. Thénard found that the cold catalyst transforms nitric oxide into ammonia and water, but J. W. Döbereiner denied this. P. Sabatier and J. B. Senderens found that spongy-palladium, previously sat. with hydrogen, exerts no action on nitric oxide in the cold, but at 200°, the mass glows and ammonia and water are formed. P. Sabatier and J. B. Senderens, and P. Néogi and B. B. Adhicary studied the effect of nickel and copper in place of platinum-black. F. Kuhlmann said that when cold spongy-platinum is exposed to a mixture of hydrogen and nitric oxide or nitrogen peroxide, it becomes red hot, and frequently gives rise to a dangerous explosion; the whole of the nitrogen is converted into ammonia. Platinum-black does not act until heated to redness, and does not become incandescent. Cold spongy-platinum does not affect hydrogen saturated with the vapour of nitric acid, but when heated, it becomes red hot and converts all the nitrogen into ammonia; platinum-black does not act unless it be heated, and even then does not become incandescent in the gaseous mixture. J. Reiset said that if the mixture be passed through a red-hot tube, ammonia is obtained only when the tube contains some porous substance like pumice-stone; ferric oxide is an energetic catalyst, while the oxides of copper, zinc, and tin are less effective. He added that the catalyst is alternately reduced and oxidized. P. A. Guye and F. Schneider showed that there are probably two concurrent reactions involved in the reduction: $2NO_2+7H_2=2NH_3+4H_2O$, and $NO_2+2H_2=N+2H_2O$, and that a temp. of 250°–300° is favourable to the former when nickel is used as a catalyst. A. C. Grubb observed that when a 3 : 1-mixture of hydrogen and nitrogen is passed about an electrode at which ozonized oxygen is being rapidly evolved, ammonia is formed, due, it is assumed, to the cumulative excitation of the collisions between atoms and free electrons as indicated by O. Klein and S. Rosseland. The hydrogen appears to be excited by the ozone, and is then capable of uniting with nitrogen. R. O. Griffith and W. J. Shutt assumed that the hydrogen remains as molecular hydrogen, and reacts with ozone to form water and oxygen.

According to J. Priestley, R. Kirwan, W. Austin, and H. Davy, nitric oxide in contact with moist iron or tin-filings, or an aq. soln. of hydrogen sulphide or alkali sulphide, is reduced, forming nitrous oxide and ammonia. I. Milner found that ammonia is formed when moist nitric oxide is passed over red-hot iron-filings; and G. Ville, when a mixture of nitric oxide and hydrogen sulphide is passed over red-hot soda-lime. M. Coblens and J. E. Bernstein found that titanous chloride reduces nitric oxide, and nitrous oxide to ammonia; but not a soln. of sodium nitrite or silver hyponitrite. Ammonia is also produced when nitric acid reacts with an excess of sodium hyposulphite. According to N. A. E. Millon, and J. F. W. Johnston, some nitric or nitrous acid is reduced to ammonia when treated with hydrogen sulphide; J. Priestley found the acid to be so reduced by tin; and W. Austin, G. Fabbroni, F. Kuhlmann, and G. Bischof, by zinc, cadmium, or iron; W. Austin found that ammonia is produced by the action of zinc or iron on copper nitrate, and G. Wetzlar, by the action of iron on silver nitrate. E. Mitscherlich, and J. F. Daniell observed that a mixture of sulphuric and nitric acids can be made to dissolve zinc, iron, or tin without the evolution of gas, but ammonium sulphate is formed. F. Kuhlmann observed that ammonia is formed when a mixture of zinc and hydrochloric or sulphuric acid acts upon potassium nitrate; in the action of ferrous sulphate on nitrous acid; in the action of ferrous hydroxide, stannous hydroxide, potassium sulphide, iron sulphide, or antimony sulphide on nitrates in the presence of dil. sulphuric acid; and by the action of hydrogen sulphide on a soln. of antimony chloride and potassium nitrate. In A. Martin's process for estimating nitrates by treatment with zinc and sulphuric acid, and conversion to ammonia, there is only a partial reduction of the nitrate; A. Pavesi found that some hydroxylamine is also formed. E. Pugh found that nitrous acid is completely transformed into ammonia by the action of a soln. of stannous chloride in hydrochloric acid at 70°—*vide infra*, nitric acid. M. Görlich and M. Wichmann treated soln. of various nitrites with hydrogen sulphide, and found that the nitrogen is also quantitatively transformed into ammonia. C. Kellner reduced a soln. of sodium nitrite with sodium-amalgam and obtained ammonia. W. Müller and E. Geisenberger prepared ammonia by passing water vapour mixed with the products obtained by calcining barium or potassium nitrate, through a retort filled with carbon; and also by heating a mixture of potassium nitrate and hydroxide, and carbon. H. E. Baudoin and E. T. H. Delort found that a mixture of sodium nitrate and hydrocarbons like naphthalene or tar gives a mixture of carbon dioxide and ammonia when heated to 800°–900°.

According to R. Ihle, the formation of ammonia at the cathode in the electrolysis of nitric acid depends on the current density and the conc. of the acid. Thus, for acids of 14·67, 28·73, 43·34, and 85·37 per cent. HNO_3, current densities of 0·00159, 0·01122, and 0·0564, and 8·6 amps. per sq. cm. were respectively required before any trace of ammonia was obtained. With increased current, the quantity of ammonia formed was also increased. J. F. Daniell noted the formation of ammonia at the cathode during the electrolysis of an aq. soln. of potassium nitrate. G. E. Cassel obtained ammonia by the electrolysis of soln. of nitrates.

According to J. W. Döbereiner, if zinc together with iron be immersed in a soln. of potassium hydroxide containing a nitrate, ammonia is formed, while if the nitrate be absent, hydrogen alone is evolved. F. Schulze showed that all the nitrate- or nitrite-nitrogen is transformed into ammonia by the action of zinc, zinc and platinum, aluminium, or sodium-amalgam on alkali soln. of nitrates or nitrites. E. J. Mills and T. U. Walton found that sulphates favour the reaction; the more sulphate present the quicker the reduction. The reaction was examined by W. Wolf, A. V. Harcourt, and M. Siewert. The reaction is rather important, because upon it is based a method for determining the quantity of nitrites and nitrates in potable water.

A mixture is made of 25 grms. of sodium hydroxide in 70 c.c. of water, 20 grms. of zinc or aluminium turnings, a piece of bright sheet iron, and 5 grms. of nitric acid in a half-litre flask, ammonia gas is slowly evolved—$4Zn+7NaOH+NaNO_3=4Zn(ONa)_2+2H_2O+NH_3$, with zinc; and $8Al+5KOH+3KNO_3+2H_2O=8KAlO_2+3NH_3$, with aluminium. The reduction of the nitric acid by the hydrogen liberated by the action of zinc on the alkaline soln. is rather too slow to make this a suitable process for making ammonia for experiments with the gas. One of the methods of preparing ammonia employed by J. S. Stas, in his work on at. wts., was to allow a conc. aq. soln. of purified potassium nitrite mixed with purified potash-lye, sp. gr. 1·25, to act for 72 hrs. on an alloy of carbon-free zinc and 5 per cent. of lead and iron wire. The clear soln. was then heated until all the ammonia was expelled.

J. Reiset found that when iron-filings are heated with a conc. soln. of potassium hydroxide, at 130°, either in air or in hydrogen contaminated with nitric oxide, both nitrogen and ammonia are evolved, but if the hydrogen be thoroughly purified, no ammonia is formed. M. Faraday found no ammonia is evolved when a mixture of potassium hydroxide and nitrate is heated, but if zinc be present, ammonia is formed; J. W. Döbereiner, that a heated mixture of potassium hydroxide and nitrate and iron-filings gives off nitrogen, hydrogen, and much ammonia; and F. Kuhlmann, that sodium sulphide and potassium nitrate at 154° give off ammonia, and similar results were obtained on heating a mixture of arsenic trisulphide, potassium hydroxide and nitrate. A mixture of ethylene, alcohol vapour, or ethyl nitrate and nitric oxide furnished ammonium cyanide when passed over heated spongy-platinum. J. W. Döbereiner showed that when a soln. of platinum in aqua regia, containing some free nitric acid, is sat. with potassium hydroxide, mixed with alcohol, and exposed to sunlight, platinum-black is deposited and some ammonia is evolved. E. T. Chapman found that some ammonia is formed when nitric oxide is reduced by a conc. soln. of hydriodic acid.

The reduction of nitrates and nitrites to ammonia by the action of bacteria was observed by M. W. Beyerinck and A. van Delden,[4] E. Crespolani, M. Gerlach and I. Vogel, E. Marchal, U. Gayon and G. Dupetit, A. Müntz, and J. Stoklasa and E. Vitek—*vide supra* for the reduction to nitrogen; and for the reduction of nitrates to nitrites.

3. *The preparation of ammonia from ammoniacal compounds.*—When ammonia gas is required for the laboratory, it may be obtained from a cylinder of liquid ammonia; by boiling aqua ammonia in a flask, or by heating an intimate mixture of commercial ammonium chloride or ammonium sulphate with twice its weight of quicklime, CaO, or slaked lime, $Ca(OH)_2$. The reaction is represented: $2NH_4Cl+Ca(OH)_2=CaCl_2+2H_2O+2NH_3$. Other mixtures are recommended by C. R. Fresenius,[5] F. Mohr, and E. Harms. Ammonia combines with the ordinary drying agents—calcium chloride, sulphuric acid, phosphorus pentoxide—and accordingly these agents must not be used with the idea of drying the gas. A tower of quicklime is generally employed. R. Bunsen used fused potassium hydroxide. If a mixture of ammonium chloride and quicklime is to be heated, an iron tube, or a copper flask, without the tube-funnel, is preferable to glass, since steam is liable to condense on the walls of the flask, trickle down, and crack the hot glass. H. Hampel and H. Steinau found that ammonia is produced when iron, ammonium chloride, and nitrogen are heated together at 300° under 50 atm. press.: $3Fe+6NH_4Cl+N_2=3FeCl_2+8NH_3$. A gaseous mixture is obtained containing up to 99 per cent. of ammonia. The portion of this derived from the ammonium chloride may be allowed to react with the ferrous chloride; the ferrous hydroxide formed is reduced and the ammonium chloride recovered for further use.

J. S. Stas, in his work on at. wts., used purified ammonium chloride for the preparation of ammonia. E. Schering purified commercial aqua ammonia by distillation from an admixture with one or two per cent. of potassium permanganate, and W. N. Hartley and J. J. Dobbie removed the pyridine from ammonia by the fractional crystallization of the oxalate, and testing the product spectroscopically. C. Matignon, H. D. Gibbs, and F. G. Keyes and R. B. Brownlee, used sodium mixed with recently fused sodium chloride to purify the ammonia and distilled off the gas. L. Moser and R. Herzner said that commercial ammonium salts always contain organic matter which can be completely oxidized by nitric acid or potassium permanganate at high temp. Ammonia can be freed from pyridine and other impurities by passage over prepared wood charcoal. A. Leduc, C. Hugot, F. E. C. Scheffer, O. Brill, G. A. Burrell and I. W. Robertson obtained ammonia for their investigations by distilling aqua ammonia one or more times, and drying it with fused alkali hydroxide. The ammonia was obtained from a cylinder of the compressed gas by L. A. Elleau and W. D. Ellis, E. C. Franklin and C. A. Kraus, H. D. Gibbs, C. Dieterici and H. Drewes, P. A. Guye and A. Pintza, E. P. Perman and J. H. Davies, G. Holst, L. Moser, and E. C. McKelvy and C. S. Taylor, and fractionally distilled one or more times. A. Vogel, and T. Weyl prepared almost dry ammonia by saturating a soln. of calcium chloride with dry ammonia, and driving off the absorbed gas by heating the soln. G. Neumann obtained a steady stream of ammonia gas by the action of solid potassium hydroxide on an aq. soln. of ammonia. E. Carey and co-workers heated an intimate mixture of ammonium and sodium sulphates: $(NH_4)_2SO_4+Na_2SO_4=2NaHSO_4+2NH_3$. In his work on the liquefaction of ammonia, M. Faraday saturated silver chloride with the gas, and afterwards expelled the gas from the amminochloride (*q.v.*) by heat. J. H. Niemann used a similar process and said that a temp. of 112°–119° is necessary to drive off the ammonia. O. Knab used calcium chloride as absorbent in place of silver chloride, and H. L. F. Melsens, wood-charcoal. E. Divers and F. M. Raoult heated the liquid obtained by saturating ammonium nitrate with ammonia.

4. *The preparation of ammonia by the action of water on nitrides, etc.*—Ammonia is formed by the action of water on various nitrogen compounds (*q.v.*)—*e.g.* nitrogen phosphide, sulphide, iodide, and chloride. Its production by the action of water on various nitrides has been previously discussed. The Titan Co.[6] prepared titanium nitride by the reduction of ilmenite in an electric furnace in the presence of nitrogen, and the product treated with dil. acid to remove the iron present, was then heated with 1·3 pts. by weight of 50 per cent. sulphuric acid at 25 atm. for 3 hrs. The nitrogen present is converted into ammonium sulphate, whilst the titanium forms titanium sulphate which immediately decomposes with quantitative precipitation of titanic oxide. G. P. Guignard recommended decomposing the nitride by steam at 360°–500°. L. Mourgeon heated a metal oxide in flue gas so as to reduce the oxide, and convert the metal into nitride. The nitride was then decomposed for ammonia. The action of superheated steam on calcium cyanamide, $CaCN_2$, also furnishes ammonia: $CaCN_2+3H_2O=CaCO_3+2NH_3$. The cyanamide is made from atm. nitrogen so that this process was employed by A. Frank, and N. Caro for the fixation of nitrogen. The Stickstoffbindungs-industrie made ammonia by the action of water at 185° and 12 atm. press. on cyanides in the presence of alkali hydroxide. In the case of lithium nitride, made from atm. nitrogen: $6Li+N_2=2Li_3N$, and its subsequent treatment with water for ammonia: $Li_3N+3H_2O=3LiOH+NH_3$, the electric energy required to convert the lithium hydroxide back to lithium appears to be about half that required to oxidize the eq. quantity of nitrogen; the loss of ammonia by absorption is small. Consequently, there are many promising features in the fixation of atm. nitrogen as ammonia by the intermediate formation of nitrides of, say, lithium, barium, calcium, aluminium, etc. L. Moser and R. Herzner obtained ammonia of a high degree of purity by allowing pure magnesium or calcium nitride to fall gradually into gas-free water. Owing to the highly exothermal character of the reaction decomposition of the gas occurs if water is allowed to fall on the nitride. The only impurity is hydrogen derived from traces of metal in the nitride. B. F. Halvorsen obtained ammonia by passing a mixture of hydrogen and hydrogen cyanide along with oxygen over a heated catalyst—*e.g.* ferric or chromic oxide at about 400°. T. T. Mathieson and J. Hawliczek[7] recovered ammonia from the cyanides present in crude soda by the action of superheated steam at 300°–500°. F. Margueritte and M. de Sourvedal employed a similar process for recovering the ammonia from the cyanides produced by heating a mixture of baryta and carbon in air; and T. B. Fogarty, from the cyanide obtained by heating a mixture of powdered coke and alkali in air or in generator gas. W. A. Nelson obtained ammonia from the nitrogen of furnace gases by heating clay, or a hydrated silicate which gives off its water at a high temp. It is believed that as the water of combination is evolved, it reacts with the nitrogen or nitrogenous compounds in the furnace gases to form ammonia. This is recovered by cooling and scrubbing the furnace gases.

5. *The production of ammonia from nitrogenous organic compounds.*—The formation of ammonia from cyanides—*vide* supplementary volume. Norsk Hydro-Elektrisk Kvaelstofaktieselskab[8] obtained ammonia by the hydrolysis of hydrogen cyanide (produced in the electric arc) by means of steam; a large excess of steam is required and the process is difficult to control. If, however, the theoretical quantity of air or oxygen is added it unites with a part of the excess hydrogen present in the gas, and hydrolysis proceeds quantitatively and evenly with only a slight rise of temp., the reaction being $HCN+H_2O=NH_3+CO$. Ferric oxide or

a mixture of ferric oxide and aluminium oxide is a suitable catalyst. The surplus gases are returned to the process after enrichment and, if air has been used, its nitrogen will serve for cyanide production. As indicated in connection with the history of ammonia, *urine* and *camel's dung* are probably the oldest sources of ammonia. Putrefied urine has been used an indefinitely long time as a source of ammonia for scouring wool, etc. Normal urine has 20–25 grms. of urea or carbamide per litre, and an adult man produces 22–37 grms. of urea every 24 hrs. During the putrefaction, the urea is changed into ammonium carbonate. The above-mentioned quantity of urea (with a little uric acid) corresponds with between 9 and 17 lbs. of ammonia per man per annum. The ammonia in *sewage* is usually too dil. for it to be profitably extracted, but in a few places the ammonia is recovered from sewage and from sludge. Several patents have been taken out in this connection—*e.g.* by J. Duncan, R. Brullé and A. Leclerc, W. F. Nast, A. Mylius, K. Wedemeyer, H. W. Seiffert, F. J. Bolton and J. A. Wanklyn, J. Young, J. C. Butterfield and G. Watson, J. B. Taylor and H. V. Walker, etc. The preparation of ammoniacal liquor from leather, scraps, etc., has been discussed by T. Richters,[9] J. Young, H. Proschwitzky, L. Tralls, and L. Sternberg. Ammonia is formed when nitrogenous compounds —*leather, bones, horn, hair, skins, and other animal refuse*—are heated in closed vessels. Animal charcoal or *char* remains in the retort, while ammonia and tar rich in pyridines pass off. The tar is known as *Dippel's bone oil,* and the ammoniacal liquor which floats on the tar is then purified—*vide infra.* An old term for ammonia —*spiritus cornu cervi,* or *spirits of hartshorn*—refers to the former custom of preparing ammonia by heating the hoofs and horns of stags, etc., in closed vessels. L. N. Vauquelin [10] observed that some ammonia is formed by heating a mixture of gum and potassium nitrate; and J. S. F. Pagenstecher, a mixture of potassium nitrate and cream of tartar. F. Varrentrapp and H. Will pointed out that if potassium hydroxide or soda-lime is present, most of the nitrogen is transformed into ammonia; and E. Schulze observed that nitrogenous organic matter gives off all its nitrogen as ammonia when heated with soda-lime. This is the principle of one of the standard methods for the determination of nitrogen in organic matter. The ammonia is absorbed in sulphuric acid. The ammonia reported by J. Woodhouse, H. Davy, and C. F. Hollunder to be formed when a mixture of potassium hydroxide and charcoal is heated is probably due to the intermediate formation of cyanides from the contained nitrogen and atm. nitrogen. M. Berthelot found that many nitrogenous organic compounds furnish ammonia when heated with hydriodic acid; and J. Kjeldahl showed that the nitrogen of many nitrogenous compounds is all converted into ammonia or ammonium sulphate when heated with conc. sulphuric acid—in the case of nitro-compounds and cyanides the reaction is not always quantitative. The reaction proceeds more satisfactorily in the presence of mercury or mercuric oxide, copper, potassium hydrosulphate, sugar, phenol, benzoic acid, and analogous compounds. This reaction has been discussed by C. Arnold, A. Atterberg, C. Budde and C. V. Schon, G. Czeczetka, L. Garnier, J. W. Gunning, G. Kreusler, P. Kulisch, L. Maquenne and E. Roux, B. Proskauer and M. Zülzer, S. Schmitz, K. Ulsch, H. Vogtherr, H. Wilfarth, etc. In 1841, J. Young proposed to recover ammonia from *guano* by mixing it with lime and heating it in a closed vessel, but the process was not remunerative. G. Vibrans [11] proposed to collect the small amount of ammonia which is evolved during the evaporation of *beetroot juice* for sugar. A comparatively large proportion is present in *vinasse, i.e.* the residue left after fermenting the sugar of molasses and distilling off the alcohol. When vinasse is distilled in a closed vessel, ammonia and trimethylamine are evolved and the residue is employed as manure or worked up for potassium salts. Patents for this have been obtained by W. Bueb, Badische Gesellschaft, L. Sternberg, E. Ernst, R. Lederer and W. Gintl, E. Meyer, etc.; and the subject has been discussed by H. Ost, J. Lajbi, and C. Vincent.

Ammonia is produced as a by-product during the dry distillation of *coal* in the manufacture of *coal-gas*, and in the manufacture of *coke* in coke-ovens. Only a small percentage of the total nitrogen of the coal is recovered in the form of ammonia, the remainder is distributed in the coke, in the tar, as cyanide in the gas and ammoniacal liquor, and as free nitrogen in the gas. The percentage amounts of the total nitrogen distributed in this manner are as follow:

	Coke.	Tar.	Cyanides.	Nitrogen.	Ammonia.
Gas-works . .	58·3	3·9	1·2	19·5	17·1
Coke-ovens . .	43·31	2·98	1·43	37·12	15·6

The gas-works data are by J. McLeod;[12] and the coke-oven data, by A. Short. The maximum yield of ammonia is obtained at about 900°–950°, and the normal production is about 20–25 lbs. of ammonium sulphate per ton of coal carbonized. With low temp. carbonization, about 450°, as in the manufacture of *coalite*, a large proportion of the nitrogen remains with the coke; at higher temp., more nitrogen is given off from the coal, primarily as ammonia, yet this is subsequently decomposed by the action of the incandescent carbon. Vertical retorts working at a higher temp. may give a higher yield than horizontal retorts because in spite of the unfavourable tendency of the higher temp. to decompose the ammoniacal vapours, the volatile products escape from the hot-zone more rapidly. If the vertical retorts are steamed during carbonization, the yield may be doubled. The use of lime, recommended by W. J. Cooper, for increasing the yield of ammonia, was abandoned because of the resulting deterioration of the coke. R. A. Mott and H. J. Hodsman discussed the factors influencing the yield of ammonia in the carbonization of coal. The extraction of ammonia from coke-oven gas, etc., was discussed by M. Mayer and V. Altmayer, H. Warth, C. Winkler, L. Mond, J. Meikle, G. Claude, Z. M. Stinnes and A. Weindel, F. W. Steere, H. A. Curtis, C. H. S. Tupholme, R. R. Tatlock, W. Heinemann, G. Reiniger, T. von Bauer, etc. In the manufacture of the so-called *producer gas* from gaseous fuel, at a higher temp., much of the ammonia is dissociated in the producer, but if the temp. is kept low, by the use of steam, much of the ammonia escapes decomposition and can subsequently be recovered. This is at the expense of the calorific value of the fuel. Ammonia is present in *blast furnace gas* when coal is used. In that case, the ammonia and tar are recovered by cooling and washing the gas. Many attempts —by H. Grouven, J. Rüderer and co-workers, W. Steger, G. W. Ireland and H. S. Sugden, A. Muntz and E. Lainé, P. Kuntze, C. Pieper, L. Casale, P. Bratt, G. Claude, E. L. Pease, K. P. McElroy, and H. C. Woltereck—have been made to recover ammonia from *peat*, but with no marked success. The subject has been discussed by A. Frank and N. Caro. Ammonia is evolved in the distillation of *oil-shales*, and it can be recovered by cooling and washing. W. Young and G. T. Beilby increased the yield of ammonia by the introduction of steam during the distillation.

The ammoniacal liquor obtained by washing the gases produced by the dry distillation of nitrogenous substances is decanted from the tar. It is a pale yellow or dark brown liquid smelling strongly of ammonia, hydrogen sulphide and phenols. Its sp. gr. is 1·01–1·03. The composition of the ammoniacal liquor varies at different stages of the process—*e.g.* the hydraulic main liquor, the condenser liquor, and the scrubber and washer liquors of the gas-works—with the nature of the coal employed, the conditions of carbonization, and the nature and method of working the plant. The qualitative composition does not vary so much. The liquid contains ammonium chloride, sulphides, carbonates, cyanide, thiosulphate, thiocyanate, and ferrocyanide. Small quantities of pyridine are present, and, according to F. W. Skirrow, 0·1–0·35 grm. of phenols per 100 c.c. The percentage amounts of the above constituents present in 100 c.c. of liquid are indicated in Table XIII, by S. E. Linder. An analogous table for German coal has been made by M. Mayer and H. Hempel. There has been some discussion as to the presence

TABLE XIII.—THE COMPOSITION OF AMMONIACAL LIQUOR (Grams per 100 c.c.)

Constituent.	Gas-works.			Coke-oven.	Blast furnaces.		Shale works.	Coalite works.
	Average.	Hydraulic main.	Condenser.	Average.	Coolers.	Washers.	Average.	Average.

of free ammonia; in many cases, the acids produced are sufficient to combine with all the ammonia; but with hydraulic main liquor collected above 60°, free ammonia is usually present. The existence of ammonium cyanide has also been questioned.

The ammoniacal liquor was formerly neutralized with sulphuric or hydrochloric acid and the soln. evaporated for the sulphate or chloride. The products were very impure, and the escaping hydrogen sulphide, etc., created a nuisance. The ammonia is now usually recovered by distillation from an admixture of the ammoniacal liquor with lime or soda-lye. The still may be heated by external firing, by internal heating with steam-coils, or, as is the common practice, by blowing live steam through the still. The ammonia evolved may be converted into sulphate, conc. gas-liquor, aq. ammonia, or liquid ammonia. The largest proportion is converted into sulphate. Stills have been described by H. Grüneberg and E. Blum,[13] A. Feldmann, G. Wilton, P. Parrish and O. W. Wright, W. M. Scott, J. Ballantyne, W. Wyld, etc.

A. Feldmann's original process is illustrated by Fig. 26. The gas liquor passes through the rectifying column *A*, and flows into the vessel, *B*, into which milk of lime is pumped at intervals, *viâ G*. At the same time the whole is kept agitated by steam injected into the mixture. The liquor, after depositing most of the lime, flows into the second column, *C*, where the ammonia liberated by the lime is distilled off. The spent liquor runs continuously away *viâ g*, and the gases and vapours pass *viâ h* into the first column, *BA*, which serves both for retaining the water, and for driving off the volatile ammonium salts in the crude gas-liquor. The saturator, *E*, and gas-ball, *F*, require no special comment. In the more recent types, only a single column is used, and modifications have been made in the method of introducing the milk of lime.

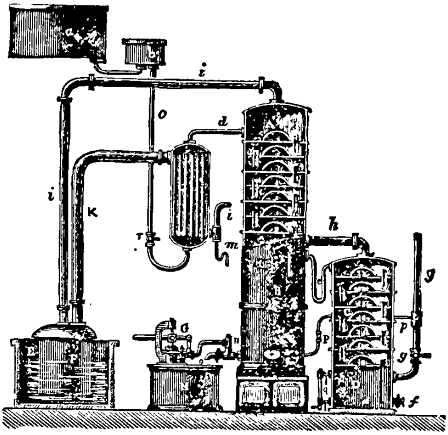

FIG. 26.—A. Feldmann's Ammonia Still.

Ammonia was formerly obtained by distilling a mixture of ammonium sulphate and lime; but it is now usually made by direct distillation of the gas-liquor so as to produce either the so-called *concentrated gas-liquor*, or the so-called *caustic ammonia*. The former has 16–26 per cent. of ammonia in the cruder product containing the sulphide, and sometimes the carbonate. It is used for the preparation of ammonium salts, and in the ammonio-soda process. To prepare caustic ammonia, a large excess of lime must be added to the gas-liquor to hold back the acid constituents including carbon dioxide and hydrogen sulphide; or, as is more usual, the vapours are passed through a set of two or three washers containing milk of lime. The last lime-washer may contain a little ferrous sulphate in soln. to remove the last traces of sulphur, or else, as recommended by O. Pfeiffer, a small extra washer containing soda-lye is added. Different types of washers have been recommended. The gases then pass through a series of scrubbers charged with wood-charcoal to remove the strong-smelling, empyreumatical matter derived from the tar—in some cases the gases are finally passed through a fatty or high boiling mineral oil to remove these empyreumatical matters. The sat. charcoal is revivified for use by heating in closed retorts. The purified gas is finally passed into distilled water to form aqua ammonia of any conc. up to 36 per cent. NH_3.

The subject has been discussed in the following works: G. T. Calvert, *The Manufacture of Sulphate of Ammonia*, London, 1911; J. Grossmann, *Das Ammoniak und seine Verbindungen*, Halle a. S., 1908; F. Muhlert, *Die Industrie der Ammoniak und Cyanverbindungen*, Leipzig, 1915; R. Arnold, *Ammonia and Ammonium Compounds*, London, 1890; V. Urbain, *Ammoniaque*, Paris, 1884; C. A. T. Villiers, *Ammonium et les sels ammoniacaux*, Paris, 1884; P. Truchot, *L'ammoniaque, ses nouveaux procédés de fabrication*, Paris, 1897; G. Schuchardt, *Die technische Gewinnung von Stickstoff, Ammoniak, und schwefelsäurem Ammonium*, Stuttgart, 1919.

In addition to the aqua ammonia of commerce, the gas is liquefied and stored in steel cylinders. Liquid ammonia is used for refrigeration. Instead of passing the gas into water, it is well dried, and liquefied by compression pumps. H. W. Foote and S. R. Brinkley[14] recommended the following method of storing and delivering dry ammonia:

The apparatus consists of a 500 c.c. wide-necked bottle fitted with a stopper carrying two tubes with taps, one for delivery and the other for charging. The bottle is nearly filled with dry ammonium thiocyanate, which acts as adsorbent. The bottle is surrounded by ice and the charging tube connected to an ammonia generator, the ammonia as it enters the bottle is absorbed about as rapidly as by water, and when the ammonium thiocyanate is sat., it contains about 45 per cent. of its wt. of ammonia. The ammonia can be drawn off by slightly raising the temp., room temp. is generally sufficiently high. This method has the advantages that the rate of evolution of the gas can be readily controlled by slight changes of temp., and also the gas evolved is dry.

According to E. Schering, some commercial samples of aqua ammonia contain ammonium carbonate, chloride, and thiocyanate, as well as pyridine, pyrrol, etc. Hence, with acetic acid, it may acquire a yellow colour, and with hydrochloric acid a red colour. H. von Strombeck reported the residue left on evaporating some samples of liquid ammonia contained water; methyl, ethyl, and isopropyl alcohols; acetone; and ammonium carbonate. In addition, mineral oil, sand, and iron oxide and sulphide were found, being accidental impurities introduced during liquefaction or from the iron containers. A. Lange and J. Hertz reported water, pyridine and some of its homologues, nicotine, ethyl alcohol, acetonitrile, ammonium carbonate, and mineral oil—and occasionally benzene and naphthalene—but they never found acetone or any alcohols other than ethyl alcohol. K. Urban reported pyrrol. J. Bougault and B. Gros found acetone. The non-condensing gases in the container were found by W. D. Richardson, and F. W. Frerichs to be mainly oxygen and nitrogen nearly in the proportions required for air; and, in some cases, hydrogen was present. A. Lange, E. C. McKelvy and C. S. Taylor, C. Ludeking and J. E. Starr, H. Bunte and P. Eitner, and R. Lucion and D. de Paepe have made observations on this subject. For the purification of ammonia from the cylinders, *vide supra.*

§ 16. The Physical Properties of Ammonia

Ammonia is a colourless gas with a pungent odour, and an alkaline taste. If inhaled suddenly, it will bring tears to the eyes; if large quantities be inhaled, suffocation may ensue. Ammonia can be condensed to a colourless, mobile liquid, and frozen to a white solid. H. E. Behnken [1] found that the **crystals** belong to the cubic system. H. Mark and E. Pohland said that the **X-radiogram** of ammonia between —77° and —160°, shows that the unit cube has 4 molecules of ammonia, and that the edge of the cube is 5·19 A. in length. J. de Smedt obtained 5·12 A. for the edge of unit cube. R. Brill said that the lattice resembles that of lithium nitride, Li_3N. As a gas, it is a little more than half as heavy as air, and consequently, the gas is collected, like hydrogen, by the downward displacement of air; the suggestion has been made to use ammonia instead of hydrogen for inflating airships. The lifting power of hydrogen is 2·3 times as great as that of ammonia, and it is but $\frac{1}{10}$th the cost; ammonia has a greater corroding action on the balloon envelope. Against these very serious disadvantages, ammonia is less inflammable, and, as liquid ammonia, it is more portable. H. Davy gave 0·5901 for the **vapour density** of ammonia—air unity; T. Thomson, 0·5931; J. B. Biot and F. J. Arago, 0·5967; and A. Leduc, 0·5971 ± 0·0002. The **litre-weight** of the gas at n.p. θ, given by J. B. Biot and F. J. Arago, is 0·7752 grm.; A. Leduc, and Lord Rayleigh gave 0·7719 grm.; and P. A. Guye and A. Pintza, 0·7708 grm.—E. Moles gave 0·7715 grm. for the best representative value. E. P. Perman and J. H. Davies said that a gram of ammonia at —20° occupies 1·19575 litres; at 0°, 1·2973 litres; at 50°, 1·5473 litres; and at 100°, 1·7964 litres. They also found that at 380 mm. press., a litre of ammonia at 0° weighs 0·3832 grm. The literature was reviewed by M. S. Blanchard and S. F. Pickering. The **specific volume** and **specific gravity** of sat. ammonia vapour are indicated in Tables XIV and XV by C. S. Cragoe, E. C. McKelvy, and G. F. O'Connor.

TABLE XIV.—SPECIFIC VOLUME OF SATURATED AMMONIA VAPOUR (c.c. per gram).

Observations were also reported by C. Ledoux, A. Berthoud, C. H. Peabody, V. Wood, G. A. Zeuner, H. Mollier, C. Dieterici, G. Wobsa, H. J. MacIntire, J. Hýbl, C. E. Lucke, G. A. Goodenough and W. E. Mosher, G. Holst, and F. G. Keyes and R. B. Brownlee. C. S. Cragoe and co-workers represented the sp. vol. of sat. ammonia vapour by $v=300(6·46344/T—0·106887+0·0356803 \log_{10}T)+0·0862366\sqrt{406·1-T}+0·002667(406·1-T)$, where v is expressed in c.c. per gram, and T in °K. The value at 60° is 48·81; at 70°, 37·78; at 80°, 29·34; at 90°, 22·75; and at 100°, 17·52. The sp. vol. of liquid ammonia was found by

M. Faraday to be 1·32 at 10°, and 1·368 at 15·5° ; P. Jolly, 1·604 at 0° ; G. Lunge, 1·626 at 20°; and A. Lange and J. Hertz, 1·47 at —38°. K. Urban also made a measurement. E. d'Andréeff gave 1·540 at —10° ; 1·555 at —5° ; 1·571 at 0° ; 1·588 at 5° ; 1·605 at 10° ; 1·623 at 15° ; and 1·642 at 20°. An extended series of observations were made by C. Dieterici and H. Drewes, A. Mittasch and co-workers, A. Berthoud, F. G. Keyes and R. B. Brownlee, and G. A. Goodenough and W. E. Mosher. The results of A. Berthoud are summarized in Fig. 27—*vide infra*, Fig. 29. J. H. Shaxby deduced a theoretical expression for the density and mol. diameter of liquid ammonia. The results of C. S. Cragoe and D. R. Harper are shown in Table XVI; they found that M. Avenarius' equation $v=3{\cdot}68+\log(130-\theta)$ gives

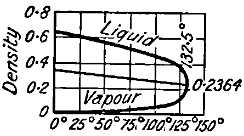

FIG. 27.—Density of Ammonia — Liquid and Vapour.

good results for the sp. vol. between —50° and 50°, where v denotes c.c. per gram, and θ in °C.; and they represented their results by:

$$v=\frac{4{\cdot}2830+0{\cdot}813055\sqrt{133-\theta}-0{\cdot}0082861(133-\theta)}{1+0{\cdot}424805\sqrt{133-\theta}+0{\cdot}015938(133-\theta)}$$

M. Faraday gave 0·74 at 10°, and 0·731 at 15·5° for liquid ammonia. P. Jolly gave 0·6234 at 0°/0°; and E. d'Andréeff, 0·6502 at —10·7°; 0·6362 at 0°; 0·6347 at 1·1°; 0·6288 at 5·4°; 0·6228 at 10·4°; and 0·6134 at 16·5°; J. Timmermans also measured the density of liquid ammonia; and A. Lange, the sp. gr., D, of liquid ammonia at different temp.; the change of vol., δv, per unit vol., $v=1$; and the mean coeff. of expansion; and his results are given in Table XVII. Observations by C. S. Cragoe and D. R. Harper on the density of liquid ammonia are indicated in Table XVIII. E. C. McKelvy and C. S. Taylor gave 0·817 grm. per c.c. for the density of solid ammonia at —79°; and 0·836 at —185°. C. H. Meyers and R. S. Jessup studied the sp. vol. of the sat. vapour.

Observations on the sp. gr. of aq. ammonia were made by J. Dalton, H. Davy, A. Ure, J. B. Richter, and J. J. Griffin, and the results for the more conc. soln. show great deviations. Tables were compiled by L. Carius, H. Hager, N. J. Price and C. S. L. Hawkins, O. Wachsmuth, H. Grüneberg, W. C. Ferguson, and J. H. Smith. G. G. and I. N. Longinescu, E. L. Nichols and A. W. Wheeler, G. T. Gerlach and H. Grüneberg, E. Baud and L. Gay, and B. S. Neuhausen and W. A. Patrick also calculated values for the sp. gr. The results of G. Lunge and J. Wiernik at 15°/4° are indicated in Table XIX. Tables for aq. soln. with 20·7, 29·9, 40·75, 42·75, 49·0, and 50·83 per cent. NH_3 at 18 temp. in the interval from 0° to 60° were calculated by A. Mitlasch and co-workers. The following is a selection from these results:

	0·3°	10·7°	20·45°	30·1°	40·0°	50·05°	60·2°

S. M. Delépine measured the sp. gr. of soln. of ammonia in aq. soln. of ethyl alcohol. I. Traube found the **molecular co-volume** of ammonia in aq. soln. is nearly 24·1. W. Herz, R. Lorenz and W. Herz, S. Mokruschin, E. Rabinowitsch, and E. Moles studied the mol. vol. A. O. Rankine estimated the mean **collision area** of ammonia molecules to be $0{\cdot}640\times10^{-15}$ sq. cm.; and R. S. Edwards and B. Worswick, $0{\cdot}633\times10^{-15}$ sq. cm. E. Mack estimated the average **radius** of the ammonia molecule to be $1{\cdot}43\times10^{-8}$ cm.; and the average **sectional area,** $6{\cdot}40\times10^{-16}$ cm. H. G. Grimm gave $0{\cdot}94\times10^{-8}$ cm. for the radius. R. Gaus discussed the structure of the molecules of the gas. G. A. Hagemann studied what he called the contraction energy of the admixture of a mol of ammonia with 50 mols of water; but, according to R. Broom, the dilution of conc. soln. of ammonia with water is attended by an expansion, and not a contraction. J. N. Rakshit calculated the contraction on diluting aq. soln. of ammonia.

M. van Marum [2] found that the vol. of ammonia did not decrease with press. in accordance with the requirements of Boyle's law. F. Roth found that if the vol. v is unity for 0° and one atm. press., thus, at 30·2°, $p=10$, $v=0{\cdot}085$; at 46·6°, for $p=10$, 12·5, and 1·5 atm., $v=0{\cdot}095$, 0·072, and 0·059, respectively; at 52·8°, $p=15$, $v=0{\cdot}040$; and

99·6°	p	12·5	15	20	25	30	40	50	60
	v	0·076	0·063	0·046	0·036	0·029	0·021	0·015	0·010
183°	p	20	30	40	50	60	70	90	100
	v	0·049	0·032	0·023	0·018	0·014	0·012	0·010	0·009

For the relation $pv/p'v'$, H. V. Regnault gave 1·01881 when $p=703{\cdot}53$, and $p'=1435{\cdot}33$; E. P. Perman and J. H. Davies, 1·0058 for $p=0{\cdot}5$ atm., and $p'=1$ atm.; and Lord Rayleigh, 1·00632 for p between 0·5 and 1 atm. A. Lange found the **compressibility** of liquid ammonia at 13°–16·2° and 17·5 atm. to be 0·000128; at 36·3°–37·3° and 16 atm., 0·000178; and at 65°–66° and 12·5 atm., 0·000304. A Jaquerod and O. Scheuer gave for the constant a in $1-p_1v_1/P_0v_0=a(p_1-p_0)$, 0·01527 when for oxygen $a=0{\cdot}00097$. P. W. Bridgman found for the press., p, in kgrms. per sq. cm.; and the change in vol., δv, in c.c. per gram of ammonia at 30°:

p	1000	2000	3000	4000	6000	8000	10,000	12,000
δv	−0·827	−0·217	0·000	0·120	0·261	0·348	0·409	0·461

There were disturbances due to the liquefaction of the gas. F. Isambert found that the coeff. of compressibility of aq. soln. of ammonia is less than that of water alone; and the more conc. the soln., the smaller the compressibility. For a litre of liquid at 21·5° containing 330 litres of dissolved gas, the coeff. was 0·0000376, and at 20·4° with 140 litres of dissolved gas, 0·0000387. Observations were also made by G. M. Maverick, and E. L. Nichols and A. W. Wheeler. O. Maass and D. M. Morrison studied the effect of molecular attraction on the total press. of ammonia; and E. Lurie and L. J. Gillespie, the equilibrium press. of mixtures of ammonia and nitrogen. F. Schuster calculated 4512 atm. for the **internal pressure** of the liquid; and J. H. Hildebrand, 3900 atm.

H. B. Dixon and G. Greenwood found the **velocity of sound** in ammonia gas at 16·5°, 41°, and 86° to be respectively 423·4, 440·8, and 470·2 metres per sec. A. Wüllner gave 415 metres per sec. at 0°; A. Masson, 416; and G. Schwerkert, 414. N. de Kolossowsky studied the relation between the velocity of sound and the velocity of translation of the molecules. K. Dörsing gave 1663 metres per sec. for the velocity of sound in conc. aq. ammonia at 16°. J. Müller found that **diffusion** of ammonia through water increased with rise of temp. and is almost inversely as the absorption coeff. A. Fujita studied the diffusion of ammonia in various soln.; H. A. Daynes, in rubber, and J. Sameshima and K. Fukaya, the atmolysis of the gas. Y. Terada measured the rate of dialysis. O. E. Meyer and F. Springmühl found the coeff. of **viscosity** of ammonia gas to be 0·000108; or 0·511 when that of oxygen is unity. A. O. Rankine and C. J. Smith gave $\eta=0{\cdot}0_4943$ at 0° and $0{\cdot}0_31303$ at 100°, when Sutherland's constant $C=370$; T. Graham gave $0{\cdot}0_4957$ at 0°, and $0{\cdot}0_31080$ at 20°; and H. Vogel, $0{\cdot}0_4957$ at 0°, and $0{\cdot}0_4686$ at −77·1°. R. S. Edwards and B. Worswick gave 370 for Sutherland's constant. E. Thomsen measured the viscosity of binary mixtures of ammonia with hydrogen and ethylene. A. Kanitz found that the viscosity at 25° of soln. containing a gram-eq. of ammonia, NH_3, in half a litre of water is 1·0490 (water unity); in a litre, 1·0245; in 2 litres, 1·0105; in 4 litres, 1·0058; and in 8 litres, 1·0030. A. Berthoud found the **surface tension** of liquid ammonia to be 23·38° dynes per cm. at 11·10°; 18·05°, at 34·05°; and 12·95, at 58·98°. The corresponding values for the mol. **surface energy,** $\sigma(Mv)^{\frac{2}{3}}$, are 213·5, 172·25, and 127·7 ergs respectively, showing that the coeff. of association between 11° and 59° is 1·27. L. L. Grunmach gave $\sigma=41{\cdot}78$ dynes per cm. at −29°, and for the **specific cohesion,** $a^2=1{\cdot}270$ sq. mm. Observations on aq. soln. were made by H. Stocker. According to J. Domke, the surface tension, σ dynes per cm., and the sp. cohesion, a^2 sq. mm., of aq. soln. of ammonia at 18° are:

NH_4OH	0	5	10	15	20	25 per cent.
σ	73·0	66·5	63·5	61·3	59·3	87·7
a^2	14·89	13·85	13·51	13·26	13·07	12·93

P. A. Guye and L. Friedrich calculated the constants in the **equation of state**: $(p+av^{-2})(v-b)=RT$, to be $a=0{\cdot}00810$–$0{\cdot}00830$, and $b=0{\cdot}00162$–$0{\cdot}00165$ in terms of the initial vol., or $a=0{\cdot}0_5401$–$0{\cdot}0_5411$, and $b=36{\cdot}7$ per mol, or $a=138{\cdot}6$–$141{\cdot}7$, and $b=2{\cdot}11$–$2{\cdot}16$ per gram. O. Knoblauch and co-workers proposed an equation of state with three constants; F. G. Keyes suggested $p=4{\cdot}877T(v-\delta)^{-1}-34610{\cdot}1(v+1{\cdot}173)^{-2}$, where $\log_{10}\delta=0{\cdot}98130-3{\cdot}08/v$. This equation was found by P. W. Bridgman to be fundamentally incompetent to represent his observations at high press. The equations of state of ammonia vapour have been studied by G. Wobsa, and M. F. Carroll. The form and structure of the ammonia molecule was discussed by F. Hund, G. Hettner, and P. W. Bridgman.

According to E. P. Perman and J. H. Davies, a gram of ammonia at −20° occupies 1·19575 litres; at 0°, 1·2973 litres; at 50°, 1·5473 litres; and at 100°, 1·7964 litres. Hence, the coeff. of **thermal expansion** at constant press. between 0° and −20° is 0·003914; 0° and 50°, 0·003854; and between 0° and 100°, 0·003847. The press. coeff. of ammonia at constant vol. between 0° and −20° was found by E. P. Perman and J. H. Davies to be 0·004003; and between 0° and 98°, 0·003802. A. Lange found the mean coeff. of expansion for liquid ammonia represented in Table XVII; and E. C. McKelvy and C. S. Taylor, 0·00007 for the mean coeff. of expansion of the solid at −185°. W. Herz discussed the relation between the internal press. and the thermal expansion. A. Winkelmann[3] found the **thermal conductivity** of ammonia gas at 100° to be 0·0000709 cal. per cm. per second per degree, and at 0°, 0·0000458; and A. Eucken gave 0·00005135 at 0° (air=0·0000566 at 0°); 0·00004410 at −36·1°; and 0·00003820 at −57·6°. C. H. Lees found the conductivity of a 25 per cent. soln. at 18° to be 0·00109. The Joule-Thomson effect has been measured by G. Wobsa, who found that the decrease in the value of the constant with increasing press. at constant temp. indicates that the compressed vapour is in the ideal state. The results were discussed by G. A. Goodenough and W. E. Mosher, and the anomalous result by G. Wobsa is attributed to the presence of 0·5–0·7 per cent. of water in the ammonia employed in the work. The **specific heat** of ammonia gas at constant press. referred to an equal weight of water was found by H. V. Regnault[4] to be $c_p=0{\cdot}512$ between 24° and 216°; F. Haber gave 0·605 at 309°; 0·65 at 422°; and 0·69 at 523°; and W. Nernst, 0·65 at 365° to 680°. E. Wiedemann gave c_p at 0°, 0·5009; at 100°, 0·5317; and at 200°, 0·5629. For the **molecular heat** at 20°, F. Keutel gave $C_p=8{\cdot}56$, and $C_v=6{\cdot}50$; K. Schöler, at 20°, $C_p=8{\cdot}86$, and $C_v=6{\cdot}80$; G. Schweikert, at 0°, $C_p=8{\cdot}85$, and $C_v=6{\cdot}77$; J. R. Partington and H. J. Cant, at 14·5°, $C_p=8{\cdot}77$, and $C_v=6{\cdot}70$; F. Voller, $C_v=6{\cdot}6$; H. B. Dixon and G. Greenwood gave:

	16·5°	41°	63·5°	86°
C_p/C_v	1·3144	1·3095	1·3062	1·3021
C_p-C_v	20·062	2·045	2·034	2·025
C_v	6·56	6·61	6·64	6·70

and W. Nernst gave $C_p=8{\cdot}62+0{\cdot}002T+0{\cdot}0_672T^{13}$, for $p=1$ atm.; and $C_v=0{\cdot}35116+0{\cdot}0001055T+0{\cdot}0_765T^{12}$. S. W. Saunders added that the published values for the mol. ht. of ammonia gas are not very concordant, particularly at high temp., $C_v=6{\cdot}65$ at 15°; 5·55 at −4·4°; and 16·5 at −80°, where the high value is supposed to be due to polymerization. F. Haber gave from ordinary temp. up to 1000° K., $C_p=8{\cdot}04+0{\cdot}00035T+0{\cdot}0000017T^2$. W. Nernst's values are rather lower, and H. Budde's results at high temp. are 16 per cent. lower than those of F. Haber. A. Wüllner gave for the sp. ht. at constant vol., 0·38026 at 0°, and 0·41635 at 100°

The ratio of the two sp. hts. was $\gamma=1\cdot3172$ at 0°, and 1·2770 at 100°; G. Schweikert gave 1·30 at 20°; A. Masson, 1·315 at 0°; A. Cazin, 1·324 at room temp.; F. Keutel, 1·317; P. A. Müller, 1·26 at 21° to 40°; J. R. Partington and H. J. Cant, 1·308 at 14·5°; and K. Schöler found 1·30 at 0·5 atm. press. and 1·41 at 3·5 atm. press. W. G. Shilling gave:

T° K.	0°	100°	200°	400°	600°	800°	1000°
C_p	8·69	8·75	9·65	10·72	11·92	13·22	14·65
C_v	6·60	6·69	7·64	8·73	9·93	11·23	12·66
γ	1·315	1·315	1·262	1·228	1·200	1·177	1·157

He also gave $C_v=6\cdot650+0\cdot00465\theta+0\cdot0_5135\theta^2$, or $C_v=5\cdot482+0\cdot00391T+0\cdot0_5135T^2$; and $C_p=8\cdot686+0\cdot00452\theta+0\cdot0_5144\theta^2$, or $C_p=7\cdot561+0\cdot00373T+0\cdot0_5144T^2$. F. A. Giacomini gave $C_v=5\cdot55$ cals. for ammonia at −44°. N. S. Osborne and co-workers measured the sp. ht. of superheated ammonia vapour between −15° and 150°, and between 0·5 and 20 atm. press. The results can be represented by the empirical equation $C_p=1\cdot1255+0\cdot00238T+76\cdot8T^{-1}+5\cdot45p10^8T^{-4}+p(6\cdot5+3\cdot8p)10^{27}T^{-12}+2\cdot37p^6 10^{42}T^{-20}$, where C_p is expressed in joules per gram at 1°; p in metres of mercury at 0° and standard gravity; and T in the temp. on the absolute scale. C. S. Cragoe determined the sp. ht. of the sat. liquid, and of the sat. vapour. Observations on the sp. ht. of liquid ammonia were made by H. von Strombeck, L. A. Elleau and W. D. Ennis, C. Lüdeking and J. E. Starr, F. K. Keyes and H. A. Babcock, C. Dieterici and H. Drewes, A. J. Wood, and F. G. Keyes and R. B. Brownlee. The sp. ht. of liquid ammonia under saturation conditions was represented by N. S. Osborne and M. S. van Dusen, by $c=0\cdot7498-0\cdot000136\theta+4\cdot0263(133-\theta)^{\frac{1}{2}}$ cals. between −45° and 45°. The observed results are indicated in Table XX. H. A. Babcock gave 1·168 at 30°; 1·222 at 50°; 1·297 at 70°; 1·431 at 90°; and 1·538 at 100°. J. Dewar gave for the sp. ht. of solid ammonia 0·5, and for the mol. ht., 8·5. E. Donath gave 8·25 at −94·5°. M. S. Wrewsky and A. I. Kaigorodoff studied the thermal capacity of aq. soln. of ammonia at different temp.; E. F. Mueller and C. H. Meyers, the **entropy**; and C. S. Cragoe, the **Joule-Thomson effect.**

In 1799, M. van Marum[5] tried the effect of press. on ammonia, and found that drops of liquid ammonia were produced at 3 atm. press. A. F. de Fourcroy and L. N. Vauquelin subjected ammonia to a low temp., and claimed to have liquefied the gas at −40°. L. B. Guyton de Morveau also cooled the gas to −43·25° and obtained liquid ammonia. In all these cases, it is doubtful if the gas was dried sufficiently to justify the inference that the drops of liquid formed on the surface of the containing vessels were really those of liquid ammonia. M. Faraday heated silver amminochloride in one leg of a sealed Λ-tube, and cooled the other leg by immersion in a freezing mixture. He thus obtained colourless, transparent, liquid ammonia; and, in 1845, by means of a mixture of solid carbon dioxide and ether, he also

TABLE XX.—SPECIFIC HEAT OF LIQUID AMMONIA UNDER SATURATION CONDITIONS (Calories at 20° per gram. per °C.).

θ° C.	0°	1°	2°	3°	4°	5°	6°	7°	8°	9°

obtained ammonia as a white, translucent, crystalline solid. The gas was also liquefied by A. Bussy. Various apparatus for the liquefaction were described by M. Faraday, R. Bunsen, L. B. Guyton de Morveau, A. Loir and C. Drion, C. G. Müller, F. P. E. Carré, C. Tellier and co-workers, S. Kern, A. Stock, etc. When ammonia gas is liquefied, heat is liberated ; and conversely, heat is absorbed when the liquid is vaporized. If liquid ammonia be evaporated, a relatively large amount of heat is absorbed from its surroundings. Advantage is taken of this fact in the preparation of artificial ice, cold storage, etc. F. P. E. Carré's *appareil propre à produire du froid* is a time-honoured application of the principle. A refrigerating plant is illustrated diagrammatically in Fig. 28. Ammonia gas is liquefied by compression in the condensing coils by means of a pump ; the heat generated as the gas liquefies is conducted away by the cold water flowing over the *condensing coils*, Fig. 28. The liquid ammonia runs into coils of pipes—*expansion coils*—dipping in brine. The press. is removed from the liquid ammonia in the expansion coils, and the heat absorbed by the rapidly evaporating liquid cools the brine below zero. The gas from the evaporating liquid is pumped back into the condensing coils ; and so the process is continuous. Cans of water placed in the brine are frozen into cakes. In cold storage rooms, the cold brine circulates in coils near the ceiling of the room to be cooled, and returns to the cooling-tank. Just as the steam engine or heat engine is an apparatus which can do work by means of the heat which is supplied to it at a high temp. and withdrawn at a low temp., the freezing machine can be regarded as a heat engine working backwards, for, by means of work, heat is withdrawn from a cold to a hotter body. In the evaporation coils of Carré's machine, the ammonia is heated and the coils are cooled ; the gas evolved is condensed in the condensing coils. There is here a fall of temp. *Absorption* takes place at a high temp., and *emission* at a lower temp. The properties of ammonia relating to refrigerating systems were discussed by W. H. Motz, S. A. Woolner, etc.

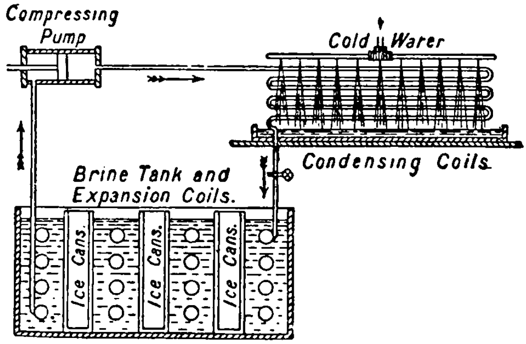

FIG. 28.—Refrigeration Plant (Diagrammatic).

According to H. Debray, between 1860–70, H. V. Regnault measured the physical constants of liquid ammonia, but the results were lost during the 1870 Franco-Prussian war. H. Debray waxes indignant :

> La main bruitale d'un soldat ennemi avait detruit, dans son laboratoire de Sèvres, les nombreux et précieux instruments de mésure qui lui avaient coute tant de labeurs et sans lequels toute recherche lui devenait impossible.

Observations on the **vapour pressure,** p mm., of liquid ammonia were made by M. Faraday, R. Bunsen, A. Blümcke, G. A. Goodenough and W. E. Mosher, H. D. Gibbs, G. Holst, R. Pictet, A. Stock and co-workers, B. Leinweber, and E. P. Perman and J. H. Davies. H. V. Regnault represented his results by the formula $\log p = 11{\cdot}504330 - 7{\cdot}4503520\alpha^{\theta+22} - 0{\cdot}9449674\beta^{\theta+22}$, where $\log \alpha = 9{\cdot}9996014 - 10$, and $\log \beta = 9{\cdot}0030729 - 10$. O. Brill found for the vap. press., p mm., of liquid ammonia :

	−79°	−70·4°	−60·8°	−50·7°	−39·8°	−33·0°
p .	38·0	74·9	212·2	309·3	568·2	761·0 mm.

and measurements by F. G. Keyes and R. B. Brownlee gave :

	−33·32°	0°	25°	50°	75°	100°	125°	132·9°
p .	760·8	3255·5	7574	15292	27857	46934	74708	(85351·8) mm.

and they represented the vap. press. between the f.p., —77°, and the critical temp., 132·9°, by the equation $\log_{10} p=-196·65T^{-1}+16·19758-0·0423858T+0·0_4 54131T^2-0·0_7 32715T^3$ mm. G. A. Burrell and I. W. Robertson represented the results by $\log p=-1951·7T^{-1}+-1·75 \log T-0·0155T+10·606$; and $\log_{10} p=-1371·86T^{-1}+8·64$; F. A. Henglein, $\log p=7·5030-2013·1T^{-1·1085}$ (p in mm.); F. Henning and co-workers, $\log p=-139360T^{-1}+1·75 \log T-0·0057034T+5·89654$; and A. Eucken and E. Karwat, $\log p=-1790·00T^{-1}-1·81630 \log T+14·97593$, for solid ammonia. R. Lorenz studied some relations of the vap. press. to other physical properties. F. Friedrichs made some observations on this subject. C. S. Cragoe and co-workers represented their results by $\log_{10} p=12·465400-1648·6068T^{-1}-0·01638646T+0·0_4 2403267T^2-0·0_7 1168708T^3$; and their data, expressed in atm. (1 atm.=760 mm. of mercury), are given in Table XXI. C. Antoine represented the vap. press. p at $\theta°$ by $\log p=1·4565\{5·4159-1000(\theta+213)\}$. V. Kirejeff discussed what he called the cohesive press. of ammonia. A. Naumann and A. Rücker observed no proportionality between the vap. press. of aq. soln., and the conc., for the partial press. decreases more rapidly than corresponds with the decrease in conc. E. P. Perman represented the relation between the partial press. of the two components—for ammonia, p, and for water, p—and the conc., x—represents the fractional number of mols. of ammonia in the liquid mixture—by $dp/dp=p_1(1-x)/px$; and this was found to co-relate the measurements fairly well. The relation between the partial press. of the water vapour and the temp., θ, was found to be $\log p=1·942+0·021950\theta-0·0000575\theta^2$ for 20 per cent. soln., and $\log p=2·051+0·0199\theta$ for 22·5 per cent. soln. A selection from the data shows:

TABLE XXI.—VAPOUR PRESSURE OF AMMONIA.

For H. Mollier's results, *vide infra*, on the solubility of ammonia. The influence of the presence of neutral salts on the vap. press. was investigated by W. Gaus, E. P. Perman, D. P. Konowaloff, and H. Riesenfeld. The rate of escape of ammonia from aq. soln. when air is aspirated at a uniform rate through the liquid was represented by E. P. Perman by $\log q=a+bt$, where q represents the amount of ammonia in the soln. at the time t; and a and b are constants—*vide infra*. D. P. Konowaloff also made observations on this subject. A. Stock and E. Pohland, and H. Reiblen and K. T. Nestle used liquid ammonia in the tensimetric determination of mol. wts. For the vap. press. of aq. soln. of ammonia, *vide infra*. A. T. Larson and C. A. Black found that the conc. of ammonia by vol. in a compressed mixture of hydrogen and nitrogen over liquid ammonia increases with increasing temp. from —22·5° to 10°, and decreasing press. from 1000 to 50 atm. There is a definite equilibrium, and the values for ammonia are greater than those calculated from the vap. press. of liquid ammonia.

R. Bunsen calculated the **boiling point** of liquid ammonia to be —33·7° at 749·3 mm. press.; M. Faraday gave about —40° at 760 mm.; F. W. Bergstrom, —33·41°; A. Loir and C. Drion, —35·7° at 760 mm.; H. V. Regnault, —38·5° at 752 mm.; R. Pictet, —33°; R. de Forcrand, —32·5°; M. W. Travers, —38·5°; A. Joannis, —38·2° at 764 mm. press.; E. P. Perman and J. H. Davies, —33·1° at 760 mm.; and F. G. Keyes and R. B. Brownlee, —33·20° ± 0·05° at 760 mm. H. D. Gibbs gave for the b.p. of liquid ammonia at different press., p, and —33·46°

p .	293	421	557	712	867	1098	1393	1726	2146	2617 mm.
B.p. .	—50°	—45°	—40°	—35°	—30°	—25°	—20°	—15°	—10°	—5°

for the b.p. at 760 mm. N. de Kolossowsky gave 0·34–0·39 for the **ebulliscopic constant.** E. C. Franklin and C. A. Kraus found that the **molecular rise of the boiling point** of liquid ammonia is $k=0{\cdot}02T^2/\lambda$ between 3·36 and 3·44—a result which is smaller than that with any other known solvent; and L. D. Elliott gave 9·7 for the **molecular lowering of the freezing point** with soln. having 0·006–0·04 mol per 100 grms. of ammonia. L. Schmid and B. Becker gave 13·18 for the f.p. constant. H. Reiblen and K. T. Nestle made observations on this subject. T. J. Webb measured the f.p. of soln. of potassium iodide, and sodium nitrate in liquid ammonia and found evidence of a little ionization. For the **melting point,** M. Faraday gave —75°; A. Ladenburg and C. Krügel, —77·05°; A. Eucken and E. Karwat, —77·5°; L. D. Elliott, —77·73° ± 0·03°; F. G. Keyes and co-workers, —77·80: and O. Brill, and E. C. McKelvy and C. S. Taylor, —77·7°. E. C. McKelvy and C. S. Taylor gave for the **triple point** constants $\theta=-77{\cdot}70°$, 44·9 mm., and $v_1=1{\cdot}363$ c.c. per gram; and $v_s=1{\cdot}224$ c.c. per gram; and vap. press., $p=45{\cdot}2$ mm. F. W. Bergstrom gave $\theta=77{\cdot}9$ and 45·5 mm. J. Timmermans also measured the f.p. of liquid ammonia. The change of temp. of freezing per atm. change of press., given by E. C. McKelvy and C. S. Taylor, is $dT=T(v_i-V_s)dp/L$, where L, the latent heat of fusion, is 108 cals. per gram, or 0·006° per atm. The small decrease instead of increase in the temp. of the f.p. is possibly due to the presence of a trace of moisture in the gas. The **latent heat of vaporization** given by H. von Strombeck was 296·5 cals. per gram; E. C. Franklin and C. A. Kraus gave 330 cals.; H. V. Regnault, 294·5 cals. at 12°; D. S. Jacobus, 290 cals. at 12°; G. Holst, 296 cals. at 12°; T. Estreicher and A. A. Schnerr, 321·27 cals. at —33·4°; D. L. Hammick, 323 cals.; and O. Brill, 321 cals. per gram. A. Eucken and co-workers gave 7120 cals. per mol. E. Donath gave 8·25 Cals. per mol at —94·5°; 8·37 Cals. per mol at —59·3°; 5999 cals. at —74·5°; and 5705 cals. at —43·9°. For solid ammonia, A. Eucken and E. Donath gave 7499 cals. at —104°, and 7440 cals. at —85°. Results for liquid ammonia were also reported by F. G. Keyes and R. B. Brownlee, C. Ledoux, H. Mollier, V. Wood, G. A. Zeuner, C. Dieterici, G. Wobsa, C. H. Peabody, H. J. Macintire, J. Hýbl, C. E. Lucke, E. Marks, G. Holst, E. Ariès, and G. A. Goodenough and W. E. Mosher; those by N. S. Osborne and M. S. van Dusen, expressed in calories per gram, are indicated in Table XXII; and the observations are sum-

marized in the formula $L=32{\cdot}968\sqrt{133-\theta}-0{\cdot}5895(133-\theta)$ cals. per gram. H. Mollier computed the heat of vaporization of aq. soln. of ammonia in Table XXIII, expressed in terms of calories per kilogram of the mixed vapour. This subject was also discussed by E. P. Perman. J. H. Shaxby studied the relation between the density, temp., and latent heat of vaporization; N. de Kolossowsky, the relation between the thermal expansion and the heat of vaporization; and W. Herz, the relation between the density and latent heat of vaporization. A. de Hemptinne applied M. Prud'homme's formula $L=KT(T_c-T)/(T_c-T_b)$, where T_c denotes the critical temp.; T_b, the b.p.; T, the temp. at which the latent heat L is observed. O. Brill gave 22·7 for **Trouton's constant**; and

TABLE XXIII.—HEATS OF VAPORIZATION OF AQUEOUS SOLUTION OF AMMONIA.

A. A. Schnerr, 22·75. R. de Forcrand, and G. Massol gave 108·1 cals. per gram for the **heat of fusion**, which is not far removed from that of water. A. Eucken and E. Karwat gave 1426 cals. per mol for the heat of fusion between 189·1° K. and 198·1° K. E. C. Franklin and C. A. Kraus have pointed out that the sp. ht. and the heat of fusion of the solid are greater than the corresponding constants for water; while the heat of volatilization, and the critical temp. and press. are higher than for any other liquid excepting water. The **molecular association** factor is as great as that of **intermolecular attraction** of ammonia. The subject was studied by E. E. Walker.

J. Dewar gave for the **critical temperature** of ammonia, 130°, and 115·0 atm. for the **critical pressure**; C. Vincent and J. Chappius gave 131·0° and 110·3 atm.; M. Centnerszwer, 132·35°; A. A. Schnerr, 132·2°; A. Jaquerod, 132·4°. F. E. C. Scheffer, 132·8° and 111·3 atm.; A. Berthoud, 132·5°–132·6° and 112 atm.; and E. Cardoso and A. Giltay, 132·90 ± 0·10°, and 112·30 atm. ± 0·10 atm. The critical opalescence was observed from 132·6° to 132·9°, with a maximum at about 132·75°. The subject was studied by W. Herz. F. G. Keyes and R. B. Brownlee gave 4·236 c.c. per gram for the **critical volume.** A. Berthoud gave for the **critical density,** 0·2362–0·2364; S. F. Pickering gave for the best representative values, T_c=405·5° K.; p_c=112 atm.; and D_c=0·236. J. A. Muller estimated the degree of polymerization in the critical state to be 1·543. The densities of ammonia, liquid and vapour, at different temp. approximate to the curve shown in Fig. 29—*vide supra*, Fig. 27; and the equation for the **mean diameter** is $\frac{1}{2}(D_v+D_1)=0{\cdot}23355+0{\cdot}0_36956(133-\theta)-0{\cdot}0_629(133-\theta)^2$. W. Herz examined the relations between the critical constants.

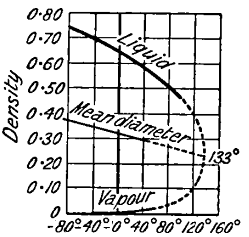

FIG. 29.—Density Curves of Ammonia — Liquid and Vapour.

B. H. Wilsdon [6] studied the energy involved in the electronic shifts during the dissociation of ammonia. J. Thomsen gave for the **heat of formation** of ammonia (N,3H)=11·89 Cals.; F. Haber, 10·95 Cals.; and M. Berthelot, 12·20 Cals. The subject was studied by R. de Forcrand. J. Thomsen gave (N,3H,Aq.)=20·3 Cals., and M. Berthelot, 21·0 Cals. A. T. Larson and R. L. Dodge calculated the following molar heats of formation from $Q_p=4{\cdot}5707(\log p_1-\log p_2)(T_1^{-1}-T_2^{-1})^{-1}$ calories:

Temp.	1	10	30	50	100 atm. press.
325°–350° . .	12,425	12,206	—	—	—
350°–375° . .	12,505	12,248	12,636	12,924	—
375°–400° . .	12,590	11,779	12,283	12,386	13,373
400°–425° . .	12,672	12.712	12,694	12,468	12,311
425°–450° . .	12,751	13,340	12,342	12,099	12,376
450°–475° . .	12,825	10,558	11,785	12,741	12,339
475°–500° . .	12,896	13,903	13,138	12,801	12,888

For the heat of combustion, J. Thomsen gave 90·65 Cals., and M. Berthelot, 91·3 Cals. The values deduced by M. de K. Thompsen for the **free energy** of ammonia at 18°, namely 45,200 cals. and 5100 cals., are incompatible—the former is based on E. Baur's observation of the e.m.f. of the cell $Pt+H_2 | NH_4NO_3$ solid, soln. of NH_4NO_3 in $NH_3 | Pt+N_2$; and the latter, on F. Haber and G. van Oordt's data for the equilibrium constant K, in $[NH_3]K=[N_2]^{\frac{1}{2}}[H_2]^{1\frac{1}{2}}$. M. Wrewsky and N. N. Sawaritzky studied the heat of formation of aq. soln. of ammonia. R. de Forcrand and G. Massol gave for the **heat of solution** of liquid ammonia, 1·882 Cals.; and G. Massol, for solid ammonia, —0·068 Cal. P. A. Favre and J. T. Silbermann gave for the heat of soln. of a mol. of ammonia in 250–370 mols. of water 8·740 Cals.; J. Thomsen, 8·440 Cals.; and M. Berthelot, 8·820 Cals. There is thus a considerable amount of heat evolved during the soln. of the gas. If a rapid current of air be driven through a cold soln. of ammonia in water, the heat absorbed as the ammonia is expelled from the soln. will reduce the temp. so as to freeze a small globule of mercury. The production of cold is best demonstrated by blowing air through a soln. of ammonia standing on a few drops of water on a block of wood. The beaker will soon be frozen to the block of wood. H. Mollier represented the heat of soln., Q, of ammonia at 15° in aq. soln. with x per cent. of ammonia, by $Q=193-1{\cdot}95x-0{\cdot}022x^2$ for values of x between 0 and 55 per cent. ammonia. Hence, $Q=0$ when $x=59{\cdot}3$. H. Mollier found for the liquid at 13°, and the gas at 15°:

x .	0	5	10	20	30	40	50	60 to 100 per cent.
Q gas	193	183	171	144	113	79	39	0 Cals.
Q liq.	493	483	471	444	413	379	339	300 Cals.

The **heat of dilution** of an aq. soln. of ammonia increases inversely as the proportion of water already in soln. increases. M. Berthelot gave the formula $Q=1270/n$

cals., for the heat of dilution, Q, in passing at 14° from $NH_3.nH_2O$ to $NH_3.200H_2O$. Thus, for $NH_3.0{\cdot}98H_2O$, the heat of dilution is 1285 cals., and for $NH_3.5{\cdot}77H_2O$, 210 cals. If Q be used to denote the heat developed per gram of ammonia when a soln. with x per cent. of ammonia is diluted to one with 0·47 per cent., H. Mollier gave $Q=79{\cdot}2x/(100-x)$. H. von Strombeck represented the amount of heat, Q, produced by the absorption of w grms. of ammonia by $Q=505{\cdot}3w$ Cals. P. Chappius gave a table of the amounts of heat developed by dissolving ammonia in water. F. Rühlemann studied the heat of soln. of ammonia in water and in alcohol. J. Thomsen gave for the heat of dilution of $NH_3.nH_2O$ to $NH_3(n+m)H_2O$ at 18°–19°, for $n=3{\cdot}2$, and $m=15$, 25, and 50, the values 324, 350, and 380 cals. respectively. W. Timoféeff found the mol. heat of soln. of 0·17–9·94 per cent. of ammonia in methyl alcohol to be 8·13–15·08 Cals.; 0·30–4·23 per cent. in ethyl alcohol, 7·03–12·30 cals.; 0·26–3·12 per cent. in propyl alcohol, 6·42–14·05 Cals.; and 0·20–3·81 per cent. in *iso*butyl alcohol, 6·04–14·40 per cent. F. E. C. Scheffer and H. J. de Wijs studied the thermodynamic potential of ammonia in soln. W. Nernst gave 3·3 for the **chemical constant** of ammonia; F. A. Henglein, and A. Langen, 2·454; S. W. Saunders, 3·4. W. Herz discussed this subject. A. Eucken and co-workers gave —1 415 for the integration constant of the thermodynamic vap. press. equation; and A. Eucken and F. Fried, 0·02 for the constant in the equilibrium equation for $3H_2+N_2=2NH_3$. A. E. van Arkel and J. H. de Boer discussed the **electronic structure** of ammonia.

The **index of refraction** of ammonia gas was measured by J. B. Biot and F. J. Arago,[7] who found 1·000381 for white light; L. Bleekrode, 1·000373; and P. L. Dulong, 1·000383. E. Mascart gave 1·000377 for the *D*-line; L. Lorenz, 0·000371; G. W. Walker, 1·000379; and E. W. Cheney gave $1{\cdot}0_33795$ for $\lambda=5852$ A.; $1{\cdot}0_33785$ for $\lambda=1{\cdot}0_33785$; and $1{\cdot}0_33771$ for $\lambda=6678$ A. C. and M. Cuthbertson found for

λ . . .	480	520·9	546·1	643·8	$670{\cdot}8\mu\mu$
μ . . .	$1{\cdot}0_338300$	$1{\cdot}0_338002$	$1{\cdot}0_337860$	$1{\cdot}0_337455$	$1{\cdot}0_337376$

S. Loria and J. Patkowsky made observations between $\lambda=435{\cdot}8\mu\mu$ and $382{\cdot}5\mu\mu$. The constants for the formula $\mu-1=C/(n_0{}^2-n^2)$ are $C'=2{\cdot}9658\times10^{27}$, and $n_0{}^2=8135{\cdot}3\times10^{27}$ for C. and M. Cuthbertson's data; and $C=2{\cdot}7898\times10^{27}$, and $n_0{}^2=7509{\cdot}8\times10^{27}$ for S. Loria and J. Patkowsky's data, C. S. Cragoe and co-workers obtained 0·0003831 at 0° and 760 mm. for the yellow He-line $\mu=1{\cdot}0016927$ at —0·33°; 1·0011592 at —10·55°; 0·0003080 at —40·67°; and 0·0001884 at —49·93°. L. Bleekrode obtained 1·325 for the index of refraction of liquid ammonia. S. Friberg obtained values for the index of refraction and dispersion in the ultra-violet. R. Lorenz and W. Herz compared the mol. refraction and the mol. vol. with those of other substances. G. Szivessy found **Kerr's constant** to be $0{\cdot}59\times10^{-10}$ at 17·9°; and C. V. Raman and K. S. Krishnan, $0{\cdot}59\times10^{-10}$ at 20° and atm. press., with the *D*-line. C. P. Smyth studied the refraction of the H_2N: radicles. K. R. Ramanathan and N. G. Srinivasan found the depolarization of light scattered by ammonia in a direction perpendicular to the incident beam is the same as it is with hydrogen chloride or sulphide. This indicates a high degree of optical symmetry. This is taken to mean that in these gases electrons of the hydrogen atoms have gone to the outer orbits of the heavier atoms to complete the electronic structure characteristic of the nearest inert gas. S. C. Lind and co-workers studied the decomposition of ammonia by α-**rays.** H. B. Wahlin examined the effect of free electrons on ammonia molecules.

A. Schuster [8] found that the **spectrum** of ammonia in the discharge tube shows a broad, greenish-yellow band between 5688 and 5627. G. Magnanini observed the spectrum of the flame of ammonia burning in oxygen exhibits a large number of hydrogen lines. This spectrum was also observed by J. M. Eder, who measured 240 lines between $\lambda=5000$ and 2262 for the extreme ultra-violet. The emission spectrum has seven characteristic bands—one between the red and ultra-violet, and the other six are in the ultra-violet. L. de Boisbaudran, D. M. Dennison, B. Hasselberg, G. Landsberg and A. Predwoditeleff, H. C. Dibbits, W. B. Rimmer, H. O. Kneser, B. J. Spense, F. Holweck, H. Deslandres, W. H. Bair, O. Reinkober, G. Hettner, H. Leupold, C. T. Kwei, K. Schierkolk, and K. B. Hofmann, observed this spectrum. The band $\lambda=3360$ observed by J. M. Eder has been studied by E. P. Lewis, who found it occurred with mixtures of hydrogen and nitrogen in vacuum tubes; and by A. Fowler and C. C. L. Gregory, who found it also occurred in the solar spectrum. The absorption of heat rays by ammonia gas was examined by J. Tyndall, G. A. Stinchcomb and E. F. Barker, P. M. Garibaldi, L. Schönn, W. J. Russell and W. Lapraik, W. de W. Abney and E. R. Festing, and W. W. Coblentz; and the absorption of ultra-violet rays, by W. N. Hartley and J. J. Dobbie, M. Ferrières, W. B. Rimmer, S. W. Leifson, and J. L. Soret. W. W. Coblentz studied the ultra-red absorption spectrum of ammonia, and found bands near 3·0μ, 6·0μ, and from 7·8μ to 15μ. K. Schierkolk resolved the last of these into a double band, and he found strong bands at 1·493μ and 1·935μ, with a weaker one at 1·643μ. There was also a strong band at 2·22μ, with two sharp maxima at 2·202μ and 2·239μ. W. F. Colby and E. F. Barker studied this subject; and B. J. Spense examined the spectrum in the vicinity of 3μ. G. Landsberg and A. Predwoditeleff studied the absorption spectrum of ammonia; and K. Glen, and E. Hulthèn and S. Nakamura, the origin of the bands. The absorption of ultra-violet rays by liquid ammonia was studied by L. Ciechomsky; and the absorption spectrum of ammonia-water, by J. L. Soret. W. N. Hartley and J. J. Dobbie attributed the band from $\lambda=2707$ to $\lambda=2322$ in commercial aq. ammonia to organic impurities.

According to M. Ascoli,[9] liquid ammonia shows the phenomenon of **electrosmose.** When a difference of potential is established between two portions of liquid ammonia separated by a porous septum of calcined alumina, and kept at a temp. of —60° by immersion in a bath of acetone cooled with solid carbon dioxide, there is usually a slight displacement of the liquid in the opposite direction to the current; but if the liquid is coloured blue by the formation of a small quantity of sodammonium in soln. there is a marked displacement of the liquid in the same direction as the current, showing that the introduction of the sodium has caused the liquid to become positively and the alumina negatively electrified.

The **electrical conductivity** of liquid ammonia is very small, and the passage of the current is accompanied by the evolution of a little gas. L. Bleekrode said that it is a good conductor; but K. T. Kemp, and J. W. Hittorf suggested that the observed conductivity of the liquid is really an effect of the presence of impurities—mainly water. C. Frenzel found the sp. conductivity of liquid ammonia of a high degree of purity to be $0{\cdot}0_{6}133$ mho at —79·3°, and $0{\cdot}0_{6}147$ mho at —73·6°, with a temp. coeff. of about 1·9 per cent. per degree. H. M. Goodwin and M. de K. Thompson obtained a sp. conductivity of $0{\cdot}0_{3}1392$ mho at —29·5°; $0{\cdot}0_{3}1485$ mho at —20°; and of $0{\cdot}0_{3}1688$ mho at —13°. The mean temp. coeff. between —30° and —12° is $dK/d\theta=0{\cdot}0_{5}11$, the increase being at the rate of about 0·7 per cent. per degree rise of temp. This is unusually small. N. Tchitchinadzé, and E. C. Franklin and C. A. Kraus also studied this subject. C. Frenzel attributed the conductivity of liquid ammonia to ionization $NH_3 \rightleftharpoons NH'_2 + H^{\cdot} \rightleftharpoons NH'' + 2H^{\cdot} \rightleftharpoons N''' + 3H^{\cdot}$, because in the curve showing the relation between the quantity and intensity of current, there are three breaks, Fig. 30. He also believed that some of the $H^{\cdot}$-ions unite with the ammonia molecules, forming $NH^{\cdot}_4$-ions. H. P. Cady showed that the mol. conductivity of salts dissolved in liquid ammonia, at its b.p. —34°, is generally greater than is the case in aq. soln. at 18°, e.g. the mol. conductivity of a soln. of potassium nitrate in liquid ammonia is 124, and in water 114 ($v=100$); potassium bromide in ammonia ($v=135$) is 181, and in water ($v=128$), only 117; silver nitrate in

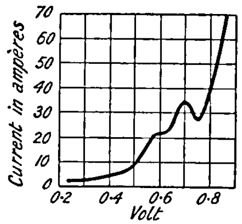

Fig. 30.—Amperage-Voltage Curves of Liquid Ammoniacal Solutions.

ammonia ($v=140$) is 147, and only 103·3 in water at a greater dilution ($v=166$). Mercuric iodide is but slightly ionized in aq. soln., but in ammonia soln. ($v=150$) the mol. conductivity is 102. H. M. Goodwin and M. de K. Thompson measured the conductivity of silver nitrate in ammonia soln. E. C. Franklin and co-workers, F. A. Smith, and P. Eversheim have examined the conductivities of many salts, etc., dissolved in liquid ammonia.

W. Hisinger and J. J. Berzelius found that the electrolysis of a conc. aq. soln. of ammonia with iron electrodes results in the evolution of hydrogen at the cathode, and nitrogen at the anode; if the soln. be less conc., oxygen may also be developed, and iron oxide formed. J. J. Berzelius and M. M. Pontin made ammonium amalgam (*q.v.*) with mercury as the negative cathode, and aq. ammonia at the anode where, during the electrolysis, oxygen was evolved. A highly purified aq. soln. of ammonia is almost as bad a conductor as purified water. M. Faraday showed that if a little ammonium sulphate be added, the aq. soln. on electrolysis furnishes between 3 and 4 vols. of hydrogen at the cathode per vol. of nitrogen at the anode. S. M. Losanitsch and M. Z. Jovitschitsch attribute the deficiency in the anodic nitrogen to the formation of nitrites in soln. F. Kohlrausch found that only when in dil. soln. does aq. ammonia behave like a normal electrolyte; and W. Ostwald represented the relation between the conductivity and the conc. of the soln. by $\tan \mu=(v/v_0)^{0\cdot4124}$, where μ represents the conductivity; v_0, the dilution—in litres per mol—at which the mol. conductivity has half its maximum value; and v, the dilution in litres per mol. The conductivity has been measured by G. Bredig, F. Kohlrausch, F. Goldschmidt, etc. G. Bredig found for the sp. conductivity, in mho, of N-soln.:

N . .	0·0109	0·0553	0·3148	0·953	2·955	4·720	12·89
Mho . .	$0{\cdot}0_31220$	$0{\cdot}0_32788$	$0{\cdot}0_36339$	0·001002	0·001296	0·001218	$0{\cdot}0_34323$

thus showing that with increasing conc., the sp. conductivity first rises to a maximum nearly 0·0013 for $3N$-soln., and then steadily falls as illustrated by Fig. 31. One of the factors concerned in the reversal of the conductivity is attributed by F. Goldschmidt to the effect of ammonia on the viscosity of the soln. observed by A. Kanitz, and the decreased mobility of the ions. Aq. soln. of salts which exert no chemical action on the ammonia have their conductivity lowered by additions of ammonia.

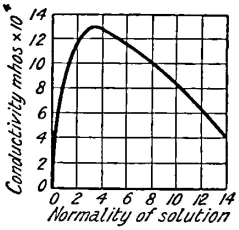

FIG. 31.—Specific Electrical Conductivity of Aqueous Solutions of Ammonia.

When ammonia is dissolved in water the deviation from Henry's law has been attributed to a chemical reaction between water and ammonia, forming *ammonium hydroxide*: $NH_3+H_2O \rightleftharpoons NH_4OH$; this inference is supported by the great difference, 3·4 Cals., between the heat of soln., 8·4 Cals., and the heat of condensation, 5·0 Cals. The 3·4 Cals. here represent the heat of admixture of a mol of ammonia with water, and this is much greater than the heat of admixture of ammonia with other liquids which do not react chemically with the ammonia. There is also a possibility that *ammonia hydrates*, $NH_3.nH_2O$, are formed, *vide infra*; and a possibility that the ammonium hydroxide is ionized $NH_4OH \rightleftharpoons NH^{\cdot}_4+OH'$. In agreement with the assumption that ammonium hydroxide is formed which acts as a weak base, the liquid tastes alkaline; it reddens turmeric; colours the juice of violets green; and colours litmus, etc., the same as do soln. of the alkali hydroxides. These changes of colour disappear on exposure to air owing to the volatilization of the ammonia—the volatile alkali of the early chemists. The feeble character of ammonium hydroxide as a base is evidenced by its heat of neutralization with acids which is about 1·5 Cals. less than is the case with potassium or sodium hydroxides; like other weak bases, the soln. cannot be satisfactorily titrated with phenolphthalein; S. Arrhenius found that its effect on the hydrolysis of ethyl acetate is about 40 times less than that of sodium hydroxide; and the electrical conductivity of aq. soln. of ammonia is small. The hydrolysis of ammonium salts was discussed by C. Brück, and E. Baars. L. Knorr explained the interaction of ammonia and ethylene oxide not as an effect of the addition of $NH^{\cdot}_4$ and OH'-ions usually assumed to be present in aq. soln., but apparently to the addition of $H^{\cdot}$ and NH'_2 or of $H^{\cdot}$ and $NH_3OH.'$ The conc. of the $H^{\cdot}$-ions in the soln. of ammonia cannot be greater than in water, owing to the presence of OH'-ions, hence, it is assumed that NH'_2 or NH_3OH'-ions are present in the soln. in addition to OH' and $NH^{\cdot}_4$-ions. B. Cassen found that Maxwell's distribution law does not hold for the motions of lithium ions in liquid ammonia.

F. Goldschmidt found that the **ionization constant,** K, varies from $0{\cdot}0_4221$ to $0{\cdot}0_623$ for $0{\cdot}0109N$- to $12{\cdot}89N$-soln. As the conc. of the soln. decreases, the value of K becomes nearly constant, as, assuming this begins with a conc. of $0{\cdot}02N$, K is 0·0000191. E. Klarmann gave 0·0000152. The inconstancy of K cannot be attributed to the formation of complex ions—*e.g.* $NH_4(NH_3)^{\cdot}$—since the lowering of the f.p. of water containing ammonia and ammonium salts corresponds with the value calculated for the quantity of material added. F. Goldschmidt found the increase in the partial press. of ammonia is almost exactly proportional to the amount of carbamide added to the soln. and the value of k calculated from $(k+[H_2O])\lambda'^2p=(k+[H^2O]')\lambda^2p'$ is negative and nearly constant. Here $[H_2O]$ denotes the active mass of water taken as 100, and $[H_2O]'$ the active mass of water after the addition of carbamide; λ and λ' are the eq. conductivities; p, p', the partial press. of ammonia of the soln. with and without the carbamide; and k represents the hydration constant. The variation of the active mass of the water is proportional to the variation of the vap. press. on the assumption that only a monohydroxide is formed. W. M. Burke measured the conductivities of soln. of ammonia at various conc. in $2M$-carbamide at 25°, and found that the ionization, as in aq. soln., conforms with the law of mass action, but the ionization constant is $12{\cdot}92\times10^{-6}$ in carbamide soln. as against $18{\cdot}1\times10^{-6}$ in aq. soln., thus presenting an exception to J. J. Thomson's hypothesis—**1.** 9, 8. The 30 per cent. difference cannot be due entirely, or to any large extent, to a change in viscosity, and it is possible that an ammonium-carbamide complex is formed which has a smaller ionization constant than ammonium hydroxide. M. Mizutani studied soln. of ammonia in water and alcohol.

A. Hantzsch and J. Sebaldt argued that if in aq. soln. ammonia exists as hydroxide, the scheme of ionization is $NH_3+H_2O\rightleftharpoons NH_4OH\rightleftharpoons NH^{\cdot}_4+OH'$, and assuming that the hydroxide is insoluble in chloroform, the conc. of ammonia, NH_3, in the aq. phase is proportional to that of the hydroxide, and the total conc. may be used in calculating the partition ratio of ammonia between water and chloroform. The partition coeff. between water and chloroform is 25 at 25°, and remains constant for varying conc., but the value changes with temp., so that at 2° the partition coeff. is 38·53. The higher the temp. the greater the proportion of ammonia in the chloroform. This is taken to mean that the ammonia is hydrated in aq. soln. forming not NH_4OH, but a complex $NH_3{\cdot}nH_2O$. R. Abegg and H. Riesenfeld measured the partial press. of ammonia in soln. of various salts, and found for conc. $0{\cdot}5$–$1{\cdot}0N$, at 25°, the partial press. was proportional to the conc. In almost all cases the addition of an alkali salt causes an increase of the partial press. of ammonia, this increase being proportional to the conc. of the salt; lithium salts are, however, exceptional. The salts may be divided into two groups, those giving a mol. increase of press. less than 2·3 and those giving a mol. increase greater than 3·4. Those giving the lower value are those containing univalent anions. The following, however, gave the higher value: hydroxides, fluorides, borates, acetates, formates, chlorates, and iodates, the action being apparently additive. The higher value appears to be connected with the tendency to form hydrates, whilst hydrates do not exist in the case of the salts for which the lower value is obtained. H. Riesenfeld compared the results at 25°, and found the only soln. for which a marked temp. coeff. exists are those of sodium and potassium carbonates, sodium and lithium chlorides. In these cases, presumably, there is interaction between the ammonia and the dissolved salt. For sodium hydroxide, potassium hydroxide, chloride, nitrate, acetate, and oxalate, the temp. coeff. is practically zero. It appears from the observations that where there is interaction between ammonia and the dissolved salt, it is greater for sodium than for potassium salts, and greater for lithium than for sodium salts. D. I. Konowaloff worked at 60°. W. Gaus worked at 23° and 27°. He found that sodium hydroxide and most ammonium salts caused, as expected, an increase of press., sodium and potassium chlorides also causing an increase. Ammonium nitrate, iodide, and thiocyanate, however, bring about a decrease of press., the cause of which may be due to the formation of complex compounds. All the other salts examined produced a decrease, which was most marked in the case of cupric and silver salts. G. S. Forbes and C. E. Norton measured the oxidation potentials of a number of organic ammonium radicles and of the alkali metals in liquid ammonia; and A. A. Groening and H. P. Cady, the decomposition potentials and metal overvoltages of soln. of salts in liquid ammonia. L. B. Loeb investigated the mobilities of ions in mixtures of ammonia and air or hydrogen.

According to G. Bredig, the velocity of migration of the $NH_4^{\cdot}$-ion at 25° is 70·4; and, according to F. Kohlrausch, 64 at 18°. The eq. conductivity $\lambda_0=271$. Assuming that $NH_4^{\cdot}$ and OH' are the only ions present in aq. soln., about 4 per cent. of a 0·01N-soln. is ionized, in a 0·1N-soln., over 1 per cent.; and in a N-soln., about 0·35 per cent. F. W. Bergstrom found the electrochemical series in liquid ammonia is Pb, Bi, Sn, Sb, As, P, Te, Se, S, I. H. P. Cady studied **concentration cells** with soln. of sodium nitrate in liquid ammonia, using sodium amalgam electrodes, and found that the laws valid for aq. soln. also apply to ammonia soln. E. Baur studied the e.m.f. of the **gas cell** with electrodes of platinum charged with hydrogen and nitrogen, and a soln. of ammonium nitrate sat. with ammonia, or a sat. aq. soln. of ammonia. The most constant results were obtained with the former liquid. At —10°, the e.m.f. is 0·59 volt. The e.m.f. falls rapidly when current is drawn from the cell, but the normal value is regained on standing, indicating that the current is produced by the union of hydrogen and nitrogen to form ammonia. He also measured the decomposition tension of the two electrolytes. G. S. Forbes and C. E. Norton measured the oxidation potentials of quaternary ammonium radicles and of alkali metals in liquid ammonia. W. Wild studied the **electrocapillary action** of soln. of potassium chloride and nitrate, mercuric nitrate, and nitric acid in liquid ammonia. A. T. Waldie obtained a critical ionizing potential at 11 volts, and possibly one at 33 volts. G. Gehlhoff studied the fall in the cathode potential by a constant discharge in a vacuum tube; L. B. Loeb and co-workers, G. C. Grindley and A. M. Tyndall, and A. T. Waldie, the mobilities of the ions in ammonia gas; and W. G. Palmer, the effect of ammonia gas on the coherer in detecting electric waves.

C. A. Mackay gave 11·1 volts for the **ionizing potential** of the gas; R. A. Morton and R. W. Riding, 11·7 volts; and A. T. Waldie, 11 volts. H. Henstock discussed the electronic structure; and L. B. Loeb, L. B. Loeb and M. F. Ashley, and H. R. Hasse, the mobilities of ions in gaseous mixtures of air and ammonia. H. M. Goodwin and M. de K. Thompson[10] found the **dielectric constant** of commercial liquid ammonia at —34° to be 21; ammonia prepared from ammonium chloride and lime, 23; and commercial liquid ammonia after dehydration, 22. C. T. Zahn found the dielectric constant, ϵ, to be:

	−71·3°	1·4°	23·7°	98·4°	183·9°
$(\epsilon-1)\times10^6$ . .	9280	7132	6117	4018	2734

He did not observe an anomaly indicated by M. Jona at room temp., but there is a definite increase near the point of liquefaction. The results can be represented by P. Debye's expression $(\epsilon-1)vT=0·000768T+1·74$, where v denotes the sp. vol. of 1 c.c. of an ideal gas at n.p. θ. C. Manneback also studied the dielectric capacity of ammonia. G. Jung discussed the orientation of the molecules in dielectric fluids; L. Ebert, the dielectric polarization; and A. Tschukareff, the magnetochemical effect in the reaction $NH_3+HCl=NH_4Cl$. K. Wolf found a discontinuity in the dielectric constant-pressure curve of ammonia when traces of moisture are present.

§ 17. The Solubility of Ammonia

Ammonia is rapidly and copiously dissolved by water; and much heat is developed. Ice also dissolves ammonia rapidly and at the same time liquefies with a reduction of temp. The rapid solubility in water has been the subject of some pretty experiments for the lecture table.[1] According to H. Davy,[2] water dissolves about half its weight of ammonia gas, or nearly 670 times its vol. at 10° and 29·8 ins. press.; and at a lower temp., J. Dalton said that water dissolves more than half its own weight of gas. Observations were also made by T. Thomson, and A. Ure. More accurate measurements were made by L. Carius, O. Wachsmuth, T. K. Sherwood, E. M. Baker, F. M. Raoult, J. W. Doyer, H. Watts, W. Gaus, E. P. Perman, and R. Abegg and H. Riesenfeld. H. E. Roscoe and W. Dittmar gave for the solubility, S, expressed in grams of ammonia per 100 grms. of water, at 760 mm.:

	0°	5°	10°	15°	20°	25°	30°	40°	50°	56°
S . .	87·5	77·5	67·9	60·0	52·6	46·0	40·3	30·7	22·9	18·5

while T. H. Sims obtained rather higher values, at 760 mm.:

	0°	10°	20°	30°	40°	50°	60°	70°	80°	90°	96°
S . .	89·9	68·4	51·8	40·8	33·8	28·4	23·8	19·4	15·4	11·4	7·4

L. Carius represented his results by $S=1049{\cdot}624-29{\cdot}4963\theta+0{\cdot}676874\theta^2-0{\cdot}0095621\theta^3$. J. W. Mallet obtained for low temp., and a press. of 743·5 mm.:

	−3·9°	−10°	−20°	−25°	−30°	−40°
S . .	94·7	111·5	176·8	255·4	278·1	294·6

The ice-curve was examined by F. Rüdorff, F. Guthrie, and S. U. Pickering; and the equilibrium curves of the binary system, by L. D. Elliot, S. Postma, F. F. Rupert, and A. Smits and S. Postma, who found:

NH_3	0	20	35	50	57·5	60	66·6	75	78	90	100 per cent.
F.p.	0°	−32°	−120°	−77°	−89°	−85·5°	−78°	−80°	−95°	−83°	−77°

$$\underbrace{0^\circ\ -32^\circ\ -120^\circ}_{\text{Ice}} \rightleftharpoons \underbrace{-120^\circ\ -77^\circ\ -89^\circ}_{NH_3.H_2O} \rightleftharpoons \underbrace{-89^\circ\ -85{\cdot}5^\circ\ -78^\circ\ -80^\circ\ -95^\circ}_{NH_3.\frac{1}{2}H_2O} \rightleftharpoons \underbrace{-95^\circ\ -83^\circ\ -77^\circ}_{NH_3}$$

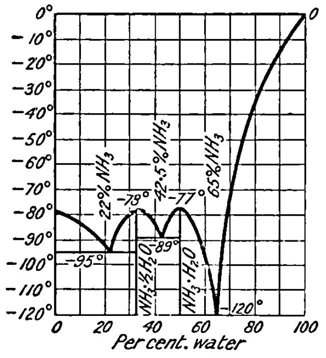

FIG. 32.—Equilibrium with the Binary System NH_3–H_2O.

The results are plotted in Fig. 32. There are thus two hydrates, **ammonia hydrate**, $NH_3.H_2O$, or **ammonium hydroxide**, NH_4OH, which forms small, colourless crystals melting at −77°. F. F. Rupert gave −79° for the m.p., and L. D. Elliot, −78·9°, and **ammonia hemihydrate**, $NH_3.\frac{1}{2}H_2O$, which forms needle-shaped crystals melting at −78°: F. F. Rupert gave −79° for the m.p., and L. D. Elliot, −79·2°. F. Friedrichs questioned the existence of these hydrates and suggested that they may be a case of mixed crystals in a continuous series. This is an *argumentum contra factum*. E. Baud and L. Gay observed maxima in curves, representing (i) the variation of the heats of dilution of ammonia with different proportions of water, and (ii) the contraction attending the dilution of ammonia with water; these maxima corresponded with the existence of a hemihydrate and a monohydrate. F. Friedrichs, W. H. Motz, G. Baume and A. Tykociner, and A. M. Wasilieff also studied the system. According to F. F. Rupert, the eutectic between NH_3 and $NH_3 \cdot \frac{1}{2}H_2O$ lies at $-94°$ with 80·3 per cent. of NH_3; and that between $NH_3 \cdot \frac{1}{2}H_2O$ and $NH_3.H_2O$, at $-87°$ and 57·3 per cent. NH_3. The effect of press. on the solubility of ammonia in water was examined by H. E. Roscoe and W. Dittmar, at 0°, and press. between 10 mm. and 2000 mm. The following are selected from T. H. Sims' results at 0°, where S denotes the number of grams of ammonia dissolved in a gram of water at the given press., p, the partial press., *i.e.* the total press. less the press. of the aq. vapour at the given temp.; and C, the number of grams of ammonia that would have been present in a gram of water if the solubility were proportional to the press.

p . .	20	100	250	500	750	1000	1500	1900
S . .	0·082	0·280	0·472	0·692	0·891	1·126	1·656	2·070
C . .	3·113	2·127	1·434	1·052	0·903	0·855	0·839	0·823

This shows that the solubility of ammonia in water is not described by Henry's law; but at 100°, the solubility data are in accord with the law:

p . .	750	800	900	1000	1100	1200	1300	1400
S . .	0·068	0·078	0·088	0·096	0·106	0·115	0·125	0·135
C . .	0·074	0·074	0·074	0·073	0·073	0·073	0·073	0·073

D. P. Konowaloff also showed that the law, invalid at ordinary temp., becomes valid at 100°. G. Calingaert and F. E. Huggins observed that the apparent deviation from Henry's law does not occur if an allowance be made for the ionization of the ammonia in aq. soln.: $NH_3+H_2O \rightleftharpoons NH^{\cdot}_4+OH'$, so that only that part of the ammonia not ionized is taken as being proportional to the conc. of the ammonia in the vapour phase. The constant for Henry's ratio with sufficiently dilute soln. is unity, and such a soln. distils without variation of conc., and corresponds to a maximum boiling mixture. The conc. of such a liquid is 0·000010 grm. of ammonia per litre. For the ratio of the partial press., p mm., and the number of mols of ammonia, n, in soln., W. Gaus, and R. Abegg and H. Riesenfeld found the deviation to be small for small conc. of ammonia. J. Locke and J. Forssall represented the relation between p and n by $p=13{\cdot}34n+0{\cdot}18n^2$. E. Klarmann observed that Henry's law applies for soln. of conc. ranging from $0{\cdot}0083N$- to $0{\cdot}5N$-NH_4OH; and said that the action in aq. soln. can be represented either by $NH_3+H_2O \rightleftharpoons NH_4OH$, and $NH_4OH \rightleftharpoons NH^{\cdot}_4+OH'$; or by $NH_3+H^{\cdot}=NH^{\cdot}_4$, and $H^{\cdot}+OH'=H_2O$. F. E. C. Scheffer and H. J. de Wijs said that the equilibrium constant of $NH_{3\text{gas}} \rightleftharpoons NH_{3\text{dissolved}}$ cannot be determined, but since for $NH_3+H_2O \rightleftharpoons NH_4OH$, $K=[NH_4OH]/[NH_3]$, so that if C denotes the total conc. of the ammonia, then $[NH_3]/C=[NH_3]/([NH_3]+[NH_4OH])=(K+1)^{-1}=$constant. The equilibrium constant of $NH_{3\text{gas}}+nH_2O \rightleftharpoons \{nNH_4OH+(1-n)NH_3\}_{\text{dissolved}}$, can be determined by means of the ratio p_{NH_3}/C, where p_{NH_3} is the press. of the gas above the liquid. Henry's law holds for conc. up to $2N$-NH_3. The vap. press., p, of the ammonia can be represented by $p=12{\cdot}9C(1+0{\cdot}046C)$. The addition of a constant small quantity (0·15 mol) of ammonium nitrate to varying conc. of ammonia has no influence on the agreement of the ratio p/C with Henry's law, or the above equilibrium conditions, but the effect of additions of increasing quantities of the salt to small conc. of ammonia can be represented by $p=12{\cdot}9C(1+0{\cdot}019C_n+0{\cdot}0085C_n^2)$, where C_n denotes the conc. of the ammonium nitrate. The subject has been discussed by E. Baars in his *Ueber den Zustand des Ammoniaks in wässriger Lösung* (Stuttgart, 1927).

E. P. Perman, and H. Mollier measured the relation between the vap. press., temp., and percentage conc. of aq. soln. of ammonia. The latter's results for the percentage conc. of the soln. at different temp. and press. are shown in Table XXIV,

and the results are plotted in Fig. 33. The total press. exerted by the vapours from soln. of different conc. and temp. are shown in Table XXV, and plotted in Fig. 34. The temp. of aq. soln. of ammonia of different conc. and vap. press. are indicated in Table XXVI, and plotted in Fig. 35. B. S. Neuhausen and W. A. Patrick represented their results by $v=0{\cdot}49(p\sigma/p_0)^{0{\cdot}69}$, where v denotes the vol. occupied by the liquid gas dissolved per gram of water; p_0, the vap. press.; p, the equilibrium gas press.; and σ, the surface tension of the liquefied gas at the given temp. R. Mezger and T. Payer measured the vap. press. of mixed soln. of ammonia and carbon dioxide. R. O. E. Davis and co-workers, E. Klarmann, W. K. Lewis and W. G. Whitman, T. A. Wilson, W. C. Sproesser and G. B. Taylor, R. T. Haslam and co-workers, O. L. Kowalke and co-workers, O. A. Hougen, W. G. Whitman and D. S. Davis measured the effect of gas velocity, temp., etc., on the rate of absorption of ammonia; and

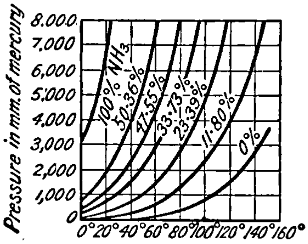

FIG. 33.—Concentration Lines for Aqueous Solutions of Ammonia at Different Temperatures.

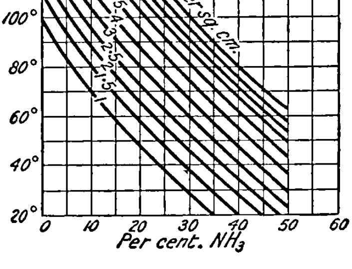

FIG. 34.—Isobaric Lines for Aqueous Solutions of Ammonia at Different Concentrations and Temperatures.

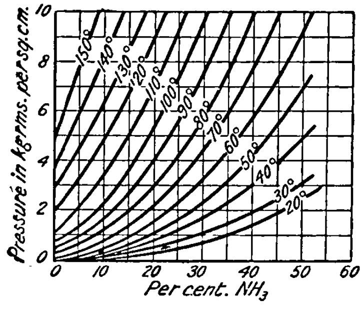

FIG. 35.—Isothermal Lines for Aqueous Solutions of Ammonia at Different Pressures and Concentrations.

P. G. Ledig, the rate of absorption from gas-bubbles. E. B. Auerbach and L. Millbradt compared the rates of escape of ammonia and water from aq. soln. They found that the loss from soln. with 34·5, 25·7, and 22·7 per cent. of ammonia was respectively 28·3, 19·4, and 16·4 per cent., while only one to two per cent. of water was lost—*vide supra.*

F. M. Raoult found the solubility of ammonia in a 11·25 per cent. soln. of *potassium hydroxide* to be at 0°, 8°, and 24° respectively, 72·0, 57·0, and 37·3 per cent.; and in a 25·25 per cent. soln., 49·5, 37·5, and 21·8 per cent. The solubility results with soln. of *sodium hydroxide* were the same as with potassium hydroxide, R. Abegg and H. Riesenfeld found that a litre of $\frac{1}{2}N$-, N-, and $1\frac{1}{2}$-N soln. of the potassium hydroxide at 25° dissolves respectively 0·852, 0·716, and 0·607 mol.; sodium hydroxide, 0·876, 0·789, and 0·716 mol ; and *lithium hydroxide,* 0·865, 0·808, and 0·768 mol. H. Riesenfeld made observations with potassium and sodium hydroxides at 35°. C. A. Lobry de Bruyn found that 100 grms. of a sat. soln. of *hydroxylamine* contain 26 grms. of ammonia at 0° and 19–20 grms. at 15°–16°. A. Waller said that when potassium hydroxide is dissolved in aq. ammonia, bubbles of gas are disengaged, but are reabsorbed in the upper portion of the liquid. R. Abegg and H. Riesenfeld found that at 25°, the solubilities of ammonia in mols per litre of $\frac{1}{2}N$-, N-, and $1\frac{1}{2}N$-soln. of the following salts are respectively as follow : *potassium fluoride,* 0·839, 0·722, 0·626 ; *potassium chloride,* 0·930, 0·866, 0·809 ; *sodium chloride,* 0·938, 0·889, 0·843 ; and *lithium chloride,* 0·980, 1·008, 1·045. H. Riesenfeld made observations with potassium and sodium chlorides at 35°. F. M. Raoult found that a soln. of *ammonium chloride* absorbs slightly less ammonia than the same vol. of water. Continuing R. Abegg and H. Riesenfeld's observations at 25°, *potassium bromide*, 0·950, 0·904, 0·857 ; *sodium bromide*, 0·965, 0·916, 0·890 ; *lithium bromide*, 1·001, 1·040, 1·090 ; *potassium iodide*, 0·970, 0·942, 0·900 ; *sodium iodide*, 0·995, 0·992, 0·985 ; and *lithium iodide*, 1·030, 1·094, 1·190. R. O. E. Davis and co-workers sought a solvent for ammonia which would not attack metals. Soln. of ammonium nitrate were recommended by B. B. Kuriloff, and of ammonium thiocyanate were recommended by H. W. Foote and M. A. Hunter; of the salts tested, *lithium nitrate* alone forms a liquid with ammonia in the absence of water, whilst *calcium nitrate* tetrahydrate liquefies in the presence of a little water. The ammonia contained in 1 c.c. of the lithium nitrate soln. sat. at 24° is eq. to 26·0 c.c. of 0·95*N*-sulphuric acid, whilst that for the calcium nitrate soln. under identical conditions is 18·5 c.c. of 0·95*N*-acid. Vap. press. measurements have been made for the soln. 36·34 per cent. ammonia, 63·66 per cent. lithium nitrate, and for several other mixtures containing 6·06–58·66 per cent. of water. The soln. of ammonia in lithium nitrate have no action on machine steel, iron wire, and nichrome wire after several months' contact, but nickel steel shows a slight action after several months. The results show that a soln. of lithium nitrate in ammonia with a small percentage of water should be a good absorbent for the removal of ammonia from mixtures of nitrogen, hydrogen, and ammonia. The absorption could be effected at 0°, and a large proportion of the ammonia released either by a small increase of temp. or by reduction of the press. D. P. Konowaloff found that the solubility of ammonia in soln. of *sodium nitrate, ammonium nitrate,* and *silver diamminonitrate* is nearly the same as in water alone. Continuing R. Abegg and H. Riesenfeld's observations, *potassium nitrate* gave 0·923, 0·862, and 0·804 ; and *potassium nitrite*, 0·920, 0·855, 0·798. F. M. Raoult showed that a soln. of sodium nitrate or *ammonium nitrate* absorbs nearly the same amount of ammonia as the same vol. of water. For a 28·38 per cent. soln. of *calcium nitrate*, F. M. Raoult gave for the solubility at 0°, 8°, and 16° respectively 96·25, 78·50, and 65·00 per cent. of ammonia ; and for a 59·03 per cent. soln. of that salt, 104·5, 84·75, and 70·5 per cent. H. Riesenfeld made observations on the solubility of ammonia in soln. of *sodium and potassium carbonates* at 35° ; and R. Abegg and H. Riesenfeld, with the soln. and units previously employed obtained for potassium carbonate, 0·788, 0·650, and 0·554. G. S. Newth, and B. S. Proctor noticed two distinct liquids are formed when conc. aq. ammonia and a sat. soln. of *potassium carbonate* are mixed, and allowed to stand. With soln. sat. at ordinary temp., the lower liquid dissolves about 37 per cent. by vol. of ammonia, and the upper liquid about 6 per cent. of the potassium carbonate soln. Working with an aq. soln. of ammonia of sp. gr. 0·885, and a soln. of potassium carbonate sat. at 25°, the solubility curve of potassium carbonate in aq. ammonia is represented by *AC*, Fig. 36, and that of ammonia in the potassium carbonate soln., by *CB*. The curves meet at 43°, so that above that critical soln. temp. the liquids are miscible in all proportions. The curves with 10 per cent. of water by vol. are shown at A_1, C_1, B_1, and the critical soln. temp. is now 25° ; and with 12·9 and 18·1 per cent. of added water, the critical soln. temp. is respectively $C_2=10°$, and $C_3=0°$. H. Riesenfeld measured the solubility of ammonia in soln. of *potassium acetate*, and *potassium oxalate* at 35°. R. Abegg and H. Riesenfeld found that at 25° the solubility of ammonia in ½*N*-, *N*-, and 1·5*N*-soln., expressed in mol of ammonia per litre, was for potassium oxalate, 0·866, 0·771, 0·675 ; potassium acetate, 0·866, 0·765, 0·685 ; *potassium formate*, 0·868, 0·760, 0·678 ; *potassium cyanide*, 0·926, 0·858, 0·802 ; *potassium thiocyanate*, 0·932, 0·868, 0·814 ; *sodium sulphide*, 0·887, 0·795, 0·726 ; *potassium sulphite*, 0·865, 0·768, 0·675 ; *potassium sulphate*, 0·875, 0·772, 0·678 ; *potassium chromate*, 0·866, 0·771, 0·675 ; *potassium borate*, 0·814, 0·677, 0·560 ; *potassium*

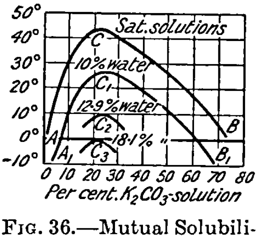

FIG. 36.—Mutual Solubilities of Aqueous Solutions of Potassium Carbonate and Ammonia.

hydrophosphate, 0·860, 0·749, 0·664 ; and for $\frac{1}{4}N$-soln. of *potassium chlorate*, 0·927 mol NH_3 ; *potassium bromate*, 0·940 ; and *potassium iodate*, 0·951. According to E. Weitz, ammonium salts of monobasic acids are in general more soluble in ammonia than in water alone ; those of polybasic acids are less soluble, and may be salted out of soln. by passing in ammonia gas. The difference is attributed to the formation of soluble ammonia additive compounds by monobasic salts, but not by polybasic salts. Fluoride, iodate, periodate, and borate behave as if the acids were polybasic, probably owing to polymerization. On the other hand, the persulphate and the dithionate show the same effect as monobasic salts, possibly because the substituted hydrogen atoms are in two distinct branches of the structural mol.

P. F. G. Boullay gave 33·3 parts for the solubility of ammonia in 100 parts of alcohol at 38° ; J. Müller said that one vol. of absolute alcohol dissolves 340 vols. of ammonia at 20° and 760 mm. ; and S. Pagliano and A. Emo said that ammonia is much less soluble in ethyl, propyl, or amyl alcohol than it is in water. C. A. Lobry de Bruyn represented the solubility of ammonia in absolute *methyl alcohol*, expressed in grams per 100 grms. of soln., by

		0°	5°	10°	15°	20°	25°	30°
S	CH_3OH . .	29·3	26·5	24·2	21·6	19·2	16·5	14·0
	C_2H_5OH . .	19·7	17·5	15·0	13·2	11·5	10·0	8·8

His results for absolute *ethyl alcohol* are also indicated. B. S. Neuhausen also studied the solubility of ammonia in methyl and ethyl alcohols. S. M. Delépine obtained values for ethyl alcohol about 4 per cent. higher ; and he measured the sp. gr. and the solubility of soln. of ammonia in aq. soln. of ethyl alcohol. Thus, he obtained :

	C_2H_5OH . .	96	90	80	60	50 per cent.
S	at 0° . .	24·5	30·25	39·0	50·45	69·77
	at 30° . .	10·7	11·4	12·2	21·2	25·25

Vide supra, for the heats of soln. of ammonia in methyl, ethyl, propyl, and isobutyl alcohols. W. Herz and H. Fischer measured the distribution of ammonia between *amyl alcohol* and water at 25° ; and, expressing the results in grams per 100 c.c., he found :

Aqueous layer . . .	0·5	1·0	2·0	3·0	4·0	5·0
Alcoholic layer . . .	0·072	0·147	0·272	0·438	0·595	0·756

H. M. Dawson and J. McCrae, and A. Hantzsch and J. Sebalt found for the distribution of ammonia between *chloroform* and water at 20° :

Aqueous layer .	0·2	0·4	0·6	0·8	1·0	1·2	1·4	1·6
Alcoholic layer .	0·007	0·015	0·023	0·031	0·039	0·046	0·055	0·063

H. M. Dawson and J. McCrae, D. P. Konowaloff, and W. Gaus also used soln. of various salts of the alkali metals, and of potassium, sodium, cupric, or barium hydroxide in place of water ; and also copper sulphate, copper chloride, zinc sulphate, and cadmium iodide ; while M. S. Sherrill and D. E. Russ examined the effect of ammonium chromate. W. Herz and A. Kurzer examined the distribution of ammonia between water and a mixture of amyl alcohol and chloroform. Observations on the distribution of ammonia between water and chloroform were made by T. S. Moore and T. F. Winmill, G. A. Abbott and W. C. Bray, and J. M. Bell. J. H. Hildebrand gave for the molar fraction $N \times 10^4$ of ammonia at 1 atm. press., and 25°, dissolved by ethyl alcohol, 2300 ; methyl alcohol, 2730 ; and water, 3300.

Ammonia is readily soluble in *ether ;* A. Christoff said that one vol. of ether at 760 mm. dissolves 17·13 vols. of ammonia at 0° ; 12·35 vols. at 10° ; and 10·27 vols. at 15°. N. T. de Saussure found that one vol. of *turpentine* dissolves 7·5 vols. of ammonia at 16° ; one vol. of *oil of lemon*, 8·5 vols. at 16° ; one vol. of *oil of rosemary*, 9·75 vols. at 29° ; one vol. of *oil of lavender*, 47 vols. at 20° ; and one vol. of *petroleum*, 0·4 vol. of ammonia. L. S. Kubie found that mineral oil at room temp. dissolves 0·071 c.c. of nitrogen per c.c. of oil. A. Hantzsch and A. Vogt found that the distribution of ammonia in grams per 1000 c.c. between *toluene* and air is at 0°, 0·366 and 0·0396 grm.; at 10°, 0·357 and 0·0435 grm.; at 20°, 0·326 and 0·0451 grm.; and at 30°, 0·286 and 0·0462 grm. C. Himly showed that one vol. of *caoutchouc* absorbs 3 vols. of ammonia; G. Cauquil, that a litre of *cyclohexanol* at 26° and 755 mm. press. dissolves 28166·66 c.c. of ammonia; and C. Gerhardt, that *valerol* absorbs much ammonia.

Recently heated *charcoal* was found by N. T. de Saussure[3] to absorb considerable quantities of ammonia, and J. Hunter showed that the raising of the temp. lowered the vol. of gas absorbed:

	0°	5°	10°	15°	20°	25°	30°	35°
Vols. NH_3 .	170·7	169·6	163·8	157·6	148·6	140·1	131·9	123·0

and the raising of the press. increased the vol. of gas absorbed:

p . .	760	1104·3	1178·0	1269·2	1369·5	1486·5	1795·1	2002·6	2608·5
Vols. NH_3 .	170·7	174·3	176·0	178·2	180·8	183·5	188·7	196·7	209·8

G. G. Longinescu and C. N. Theodosu, H. Franzen and O. von Meyer, P. A. Favre, P. Chappius, O. Ruff and G. Rösner, R. Chaplin, A. Magnus and C. Cahn, and E. W. R. Pfeiffer also studied the effects of temp. and press.—*vide* **5**. 39, 9—and F. G. Keyes and M. J. Marshall gave 6456 cals. per mol for the heat of absorption on charcoal. P. Chappius examined the absorption of ammonia by *asbestos* and *meerschaum;* E. H. Jenkins, by *gypsum;* L. Y. Davidheiser and W. A. Patrick, by *silica gel;* L. A. Munro and F. M. G. Johnson, by *alumina;* and N. Nikitin, by alumina, *chromic oxide*, and *ferric oxide;* D. H. Bangham and F. P. Burt, and M. Crespi and E. Moles, by *glass;* R. Seeliger, by dehydrated *chabazite;* and W. A. Dew and H. S. Taylor, by *copper*, *nickel*, and *iron*. J. D. Edwards and S. F. Pickering found that if the permeability of *rubber* to hydrogen is unity, the value for ammonia is 8·0.

In the following survey of the behaviour of different substances in liquid ammonia, the observations of G. Gore[4] are indicated by "G.," and those of E. C. Franklin and co-workers, by "F."; v.s. is put for "very soluble"; s. for "soluble"; s.s., "sparingly soluble"; n.s. for "insoluble"; and m. for "miscible." **Aluminium**: metal, n.s., G.; chloride, n.s., F.; acetate, n.s., F. **Ammonium**: acetate—L. Troost; arsenate, n.s., F.; bromide, v.s., F.; borate, s.s., F.; bromide, v.s., F.; carbonate, n.s., G. and F.; chloride, v.s., G. and F.; chromate, s.s., F.; hypophosphate, s., F.; iodide, v.s., F.; molybdate, n.s., F.; nitrate, v.s., G. and F.; orthophosphate, n.s., F.; selenate, n.s., F.; sulphate, n.s., F.; sulphide, v.s., F.; thiocyanate, v.s., F.; vanadate, n.s., G.; oxalate, n.s., F.; oxalurate, s., F.; and thionurate, s., F. H. Moissan found sulphammonium easily soluble in liquid ammonia; and E. Rengade, ammonium carbamate to be soluble. H. Stamm discussed the solubility of ammonium salts in ammonia. **Antimony**: metal n.s., G.; bromide, v.s., G.; trichloride, swells, n.s., G.; fluoride, swells, n.s., G.; iodide, reacts, G.; oxide, n.s., G.; hydrated pentoxide, s.s., G.—see A. Rosenheim and F. Jacobsohn; oxybromide, s.s., G.; oxychloride, unchanged, G.; red sulphide, n.s.; orange sulphide, s., G.; black sulphide, n.s., G.; tartrate, n.s., F.; and potassium pyroantimonate, n.s., G. **Arsenic**: metal, n.s., G. and F.; amide, n.s., C. Hugot; arsenious acid, n.s., G. and F.; potassium arsenide, n.s., C. Hugot; arsenic acid, s.s., G.—see A. Rosenheim and F. Jacobsohn; tribromide, swells, C. Hugot; trichloride, reacts, G. and F.; auripigmentum, s.s., G. and F.; and realgar, s., G. **Barium**: metal, n.s., G. A. Guntz and R. C. Mentrel; amide, n.s., R. C. Mentrel; carbonyl, n.s., R. C. Mentrel; chloride, swells, n.s., G. and F.; nitrate, v.s., G., s., F.—see F. Friedrichs; nitride, n.s., R. C. Mentrel; oxide, n.s., G.; hydroxide, n.s., G. and F.; sulphate, n.s., G. and F.; and acetate, s.s., F. **Beryllium**: carbonate, chloride, oxide, and sulphate, n.s., G. **Bismuth**: metal, n.s., G.; carbonate, n.s., G.; chloride, s., G.; oxychloride, n.s., F.; fluoride, n.s., G.; hydroxide, n.s., G.; iodide, s.s., F.; nitrate (soluble in presence of ammonium nitrate) and sulphide, n.s., G. **Boron**: element, n.s., G.; amide, s., J. A. Joannis; chloride and bromide, react; imide, n.s. A. Stock and M. Blix's, and J. A. Joannis' imide is soluble in the presence of sulphur; nitride—see A. Stock and M. Blix; oxide, n.s., G.; boric acid, s.s., F.; and sulphide, reacts, A. Stock and M. Blix. **Cadmium**: bromide, n.s., G. and F.; carbonate, n.s., G.; chloride, n.s., G. and F.; fluoride, n.s., G.; iodide, n.s., G., s.s., F.; nitrate, s., F.; sulphate, n.s., F.; and sulphide, n.s., G. and F. **Cæsium**: metal, v.s., H. Moissan; alum, n.s., F.; acetylide, s., H. Moissan; carbide—see H. Moissan; and hydride, reacts, H. Moissan. **Calcium**: metal, n.s., G., s.s., H. Moissan; amide—see H. Moissan;

bromide, s.s., F.; carbonate, n.s., F.; chloride, n.s., F. and G.; nitrate, v.s., F.; oxide, orthophosphate, sulphide, sulphite, formate, and butyrate, n.s., F.; polysulphide, n.s., H. Moissan; and acetate, s.s., F. **Carbon:** wood-charcoal, and graphite, n.s., G.; carbonyl chloride, reacts, F.; dioxide—see E. Rengade; monoxide—see J. A. Joannis; hexachloride, n.s., G.; tetrabromide, v.s., G.; tetrachloride, m., G. and F.; disulphide, reacts, G. and F.; acetylene—see H. Moissan; amylene, not miscible, G.; diisoamylene, n.s., F.; hexane, n.s., F.; paraffin, n.s., G.; benzene, s., F.; naphthalene, s.s., G. and F.; and anthracene, n.s., G. and F. **Cerium:** chloride, fluoride, and oxide, n.s., G.; and nitrate, s.s., G. and F. **Chromium:** chloride, swells, s.s., G.; fluoride, n.s., G.; chromic acid, swells, s.s., G., s.s., F.; and chrome-alum, n.s., G.—see A. Rosenheim and F. Jacobsohn. **Cobalt:** carbonate, n.s., G.; chloride, and sulphate, n.s., F. and G., swells, G.; fluoride, n.s., G.; nitrate, s., F.; and oxide, n.s., G. and F. **Columbium:** columbic acid, n.s., G. **Copper:** metal, reacts, G. and F.; ammonium chloride, s.s., F.; arsenate, and arsenite, n.s., F.; carbonate, n.s., G. and F.; chloride, swells, n.s., G., and n.s. A. Bouzat; cuprous chloride, s.s., F.; chromate, n.s., G.; cyanide, s., G.; cuprous cyanide, s., G.; ferrocyanide, n.s., G.; fluoride, n.s., G.; cuprous iodide, n.s., G.; v.s., F.; nitrate, v.s., F.—see F. Friedrichs; oxide, reacts, G. and F.; cuprous oxide, reacts, G., phosphate, n.s., G.; cryst. sulphate, n.s.; anhydrous sulphate, n.s.. swells, G., n.s., A. Bouzat; sulphide, n.s.; acetate, s.s., F.; formate, s.s., F.; and benzoate, s., J. A. Joannis. **Didymium:** nitrate, s., F. **Gold:** chloride, reacts, s.s., G. **Indium:** metal, n.s., G.; black oxide, n.s., F. **Iodine:** element, s., F. and G.—see F. Friedrichs; iodic acid, n.s., G. and F., and nitrogen iodide, n.s., C. Hugot. **Iridium:** potassium chloroiridate, osmium-iridium alloy; and iridium oxide, n.s., G. **Iron:** metal, n.s., G.; ferricbromide, s.s., F.; iodide, v.s., F.; pyrophosphate, n.s., F.; and sulphate, swells, n.s., G.; *ferrous*-potassium cyanide, no change, G., n.s., F.; sulphate, n.s., F.; sulphide, n.s., F.; lactate, s.s., F.; valerianate, s.s., F. **Lanthanum:** sulphate, n.s., G. **Lead:** metal, n.s., G.; bromide, s., F.; carbonate, n.s., F.; chloride, swells, n.s., G., s.s., F.; chromate, n.s., G. and F., dichromate, s.s., G. and F.; fluoride, n.s., G.; iodide, s.s., G., v.s, F.; nitrate, s.s., G. and F.—see F. Friedrichs; litharge, n.s., F.; red-lead, n.s., G. and F.; dioxide, n.s., F.; galena, n.s., F.; acetate, v.s., F.; formate, s., F.; and tartrate, n.s., F. **Lithium:** metal, s., G., F., and H. Moissan; amide, s.s., H. Moissan; antimonide, s., P. Lebeau; bromide, s., F.; carbonate, n.s., F.; chloride, s.s., F.; iodide, v.s., F.; methyl ammonium, s., H. Moissan; nitrate, v.s., F.; benzoate, v.s., F.; and salicylate, v.s., F. **Magnesium:** metal, n.s., G.; bromide, s.s., F.; carbonate, n.s., F.; oxychloride, s.s., F.; cyanamide, s., F.; iodide, v.s., F.; nitrate, v.s., F.; oxide, phosphate, sulphate, sulphide, and sulphite, n.s., F.; acetamide, s., F.; and benzoy-sulphamide, s., F. **Manganese:** metal, n.s., G.; bromide, and carbonate, n.s., G. and F.; chloride, n.s., G. and F.; fluoride, n.s., G.; iodide, s., F.; nitrate, v.s., F.; sulphate, n.s., G. and F. **Mercury:** metal, n.s., G.; bromide, s.s., reacts, G.; chloride, s., G. and F.; mercurous chloride, v.s., G.; cyanide, v.s., G. and F.; iodide, v.s., G. and F.; mercurous iodide, v.s., F.; nitrate, s., G. and F., reacts, G.; mercurous nitrate, v.s., G. and F.; yellow oxide, n.s., F. and G., but soluble in the presence of ammonium nitrate; red oxide, n.s., G.; mercurous oxide, n.s., F.; thiocyanate, v.s., F.; sulphate, s.s., G., n.s., F.; cinnabar, n.s., G.; fulminate, v.s., F.; and mercurous acetate, v.s., G. and F. **Molybdenum:** metal, n.s., G. and F.; molybdic acid, n.s., G. and F.; and sulphide, n.s., G.—see A. Rosenheim and F. Jacobsohn. **Nickel:** metal, n.s., G.; chloride, swells, G., n.s., G. and F.; fluoride and hydroxide, n.s., G.; nitrate, s., F.; oxide, n.s., G.; and sulphate, n.s., F. **Nitrogen:** no reaction, J. A. Joannis; nitric and nitrous oxides—see J. A. Joannis; iodide, n.s., C. Hugot. For ammonium iodide, bromide, chloride, azide, and carbonate, and hydroxylamine chloride, and hydrazine chloride—see F. Friedrichs. **Osmium:** metal, n.s., G.; osmium-iridium alloy, n.s., G.; and osmic acid, reacts, G. **Palladium:** metal, n.s., G.; chloride, s.s., G.; and sulphide, n.s., G. **Phosphorus:** red, n.s., G. and F.; white, s., G. and F; trichloride, reacts, G. and F.; pentachloride, reacts, F., v.s., G.; pentoxide, s.s., G., n.s., F.; amide—see J. A. Joannis; nitride—see A. Stock and B. Hofmann; hydride—see J. A. Joannis; phosphoric acid, no change, and pentasulphide, s., A. Stock and B. Hoffmann. **Platinum:** metal, n.s., G.; platinous chloride, s.s., G.; chloride, s.s., G.; iodide, v.s., G.; and oxide, n.s., G. **Potassium:** metal, s., G. and F.; amide, v.s., J. A. Joannis, pyroantimonate, n.s., F.; arsenide, s., C. Hugot; tetrarsenide, v.s., C. Hugot; bromide, s.s., G., s., F.; carbonate, n.s., F.; carbonyl—see J. A. Joannis; chlorate, s., F.; chloride, s.s., G. and F.; chloroiridate, n.s., F.; chromate, s.s., G., n.s., F.; dichromate, s.s., G. and F.; cyanate, v.s., F.; cyanide, n.s., G.; s., F.; ferrous cyanide, n.s., G. and F.; fluoride, s.s., G.; fluosilicate, n.s., G.; fluozirconate, n.s., G.; hydride—see H. Moissan; hydroxide, n.s., F.; hypophosphite, s.s., F.; iridate, n.s., G.; iodate, n.s., F.; iodide, s.s., G. and F.—see F. Friedrichs; nitrate, s.s., F.; nitrite, s.s., F.; oxide, dioxide, and tetroxide, n.s., F.; permanganate, v.s., G. and F.; metaphosphate, n.s., F.; pentaphosphide, v.s., C. Hugot; hydrophosphide, s.s., J. A. Joannis; thiocyanate, s., G. and F.—see F. Friedrichs; selenide, n.s., C. Hugot; tetraselenide, s., C. Hugot; sulphamide, v.s., F.; sulphate, n.s., F.; sulphide, s., F., n.s., C. Hugot; pentasulphide, s., C. Hugot; sulphite, n.s., F.; telluride, n.s., C. Hugot; trinitride—see J. A. Joannis; tritelluride, s., C. Hugot; acetate, s.s., F.; ethyl sulphate, v.s., F.; benzolsulphate, s., F.; orthonitrophenolsulphate, s., F.; nitroprusside, v.s., F.; formate—see E. Rengade; acetamide, v.s., F.; benzamide, s., F.; benzoylsulphamide, s., F.; urea, s., F.; *m*-methoxybenzoylsulphamide, s.s., F.; phenylacetamide, v.s., F.; saccharine, s., F.; and *p*-toluosulphamide, s.s., F. **Rubidium**: metal, s., G., F., and H. Moissan; acetylide, s., H. Moissan; carbide—see H. Moissan; chloride, s.s., F.; and fluoride, n.s., G. **Selenium**: no change, G., s., F.; n.s., C. Hugot; selenious acid, n.s., G.; selenic acid, n.s., F. **Silver**: metal, n.s., G.; arsenate, n.s., G.; bromide, swells, s.s., G., s., F.—see F. Friedrichs; carbonate, swells, n.s., G., n.s., F.; chloride, swells, G., s.s., F.—see F. Friedrichs; chromate, n.s., G.; cyanide, v.s., G. and F.—see F. Friedrichs; fluoride, s.s., G.; iodate, n.s., G.; iodide, v.s., G. and F.; nitrate, v.s., G. and F.—see F. Friedrichs; nitrite, v.s., F.; azide—see F. Friedrichs; oxide, swells, n.s., G.; n.s., F.; dioxide, n.s., G.; phosphate, n.s., G.; sulphate, swells, n.s., G., n.s., F.; vanadate, n.s., G.; acetate, s.s., F.; and thioethylcarbamate, n.s., F. **Silicon**: amide, n.s., E. Vigouroux and C. Hugot; disulphide, reacts, M. Blix and W. Wirbelauer; sulphochloride, reacts, M. Blix and W. Wirbelauer; sulphourea, n.s., M. Blix; tetrachloride, reacts, M. Blix and C. Hugot; crystalline silica, n.s., G.; precipitated silica, n.s., G. **Sodium**: metal, s., G. and F.; amide, and antimonide, s.s., J. A. Joannis; arsenide, s., C. Hugot; diborate, n.s., F.; lead alloy, s., J. A. Joannis; bromate, s., F.; bromide, v.s., F.—for sodium bromide, and azide, see F. Friedrichs; carbide, s., H. Moissan; carbonate, n.s., F.; carbonyl—see J. A. Joannis; chlorate, v.s., F.; chloride, s.s., G., s., F.; dichromate, s.s., F.; hydroxide, n.s., F. N. Tchitchinadzé found 2·5 mgrms. of sodium hydroxide are dissolved per 1000 grms. of liquid ammonia, or 1·8 mgrms. per litre, and the solubility is much augmented if moisture be present; hyponitrite—see J. A. Joannis; hypophosphate, s.s., F.; iodide, and nitrate, s.s.; trinitride, J. A. Joannis; nitride, v.s., F.; oxide, dioxide, and trioxide, n.s., J. A. Joannis; permanganate, s.; pyrophosphate, n.s., F.; triphosphide, v.s., C. Hugot; phosphomolybdate, n.s., F.; hydrophosphide, s., J. A. Joannis; and $Na_3H_3P_2$, s.s., C. Hugot; selenide, n.s., C. Hugot, tetraselenide, s., C. Hugot; sulphate and hydrosulphate, n.s., F.; sulphide, n.s., C. Hugot; pentasulphide, s., C. Hugot; sulphite, n.s., F.; telluride, n.s., C. Hugot; tritelluride, s., C. Hugot; thiosulphate, s., C. Hugot; bismuthide, s.s., C. Hugot; tungstate, s.s., F.; acetate, s.s., F.; formate, s.s., F.; ethylsulphate, v.s., F.; benzoylsulphinate, s., F.; carbamate, n.s., E. Rengade; citrate, n.s.; propionate, s.s., F.; salicylate, v.s., F.; valerianate, n.s., F.; and *o*-xylenesulphinate, s. **Strontium**: metal, n.s., G., s.s., A. Guntz; carbonate, n.s., F.; chloride, n.s., F.; nitrate, v.s., F.—see F. Friedrichs; and sulphate, n.s., F. **Sulphur**: element, s., G. and F.—see F. Friedrichs; chloride, s., G. and F.; iodide, v.s., F.; carbide, reacts, G. and F.; nitride, v.s., O. Ruff and E. Geisel; sulphamide, v.s., F. **Tellurium**: n.s., F., G., and C. Hugot; nitride—see R. Metzner; tetrachloride, reacts, R. Metzner. **Thallium**: metal, n.s., G. and F.; chloride, n.s., F.; fluoride, n.s., G.; nitrate, s., F.; peroxide, n.s., G. **Thorium** sulphate, n.s., G. **Tin**: metal, monoxide, and dioxide, n.s., G.; dichloride, s., G.—see F. Friedrichs; and tetrachloride, v.s., G. **Titanium**: nitrocyanide, black oxide, and dioxide, n.s., G.; and tetrachloride—see M. Blix. **Tungsten**: metal and oxide, n.s., G.—see A. Rosenheim and F. Jacobsohn. **Uranium** fluoride, s.s., G., nitrate and oxide, react, G.—see A. Rosenheim and F. Jacobsohn. **Vanadium**: nitride and oxide, n.s., G. **Zinc**: bromide, swells, n.s., G., s.s., F.; carbonate, n.s., F.; chloride, swells, n.s., G., n.s., F.; chromate, n.s., F.: cyanide, s.s., G., v.s., F.; ferrocyamide, s.s., F.; fluoride, n.s., G.; iodide, swells, n.s., G., s., F.; nitrate, s.s., F.; oxide, phosphate, sulphide, and sulphate, n.s., F.; acetate, s., F.; lactate, v.s., F.; and tartrate, n.s., F. **Zirconium**: metal, and oxide, n.s., G.; and tetrachloride—see M. Blix.

The following qualitative observations on the action of liquid ammonia on organic compounds are mainly by E. C. Franklin and C. A. Kraus, those in brackets are by G. Gore. *Aliphatic compounds.*—**Halides**: methyl iodide, m.; chloroform, reacts, and m.; bromoform, m.; iodoform, v.s., ethyl bromide and iodide, s.; ethylene bromide, s.; ethylidene chloride, m.; isobutyl bromide, s.; amyl bromide, s.s.; tribromomethane, v.s.; nitrotrichloromethane, m.; perchloroethane (n.s.); perchloroethylene (m.); dichloroacetylene (s.). **Alcohols**: methyl, m.; ethyl, m.; propyl, m.; normal butyl, m.; isobutyl, m.; tertiary butyl, m.; amyl, m.; heptyl, m.; octyl, m.; cetyl, n.s.; ethylene glycol, m.; propylene glycol, m.; glycerol, m.; erythrite, s.s.; dulcite, s.s.; and mannite, s.s. **Ethers**: diethyl other, m.; diamyl ether, s.s.; and methylal, m. **Aldehydes**: acetaldehyde, m.; paraldehyde, m.; aldehyde ammonia, s.; chloral hydrate, s.; bromal hydrate, v.s.; chloral cyanhydrate, v.s.; isobutyl aldehyde, v.s.; valeraldehyde, v.s.; heptylaldehyde, s.; glyoxal, n.s.; pinacone, v.s.; and oxymethylene, n.s. **Monobasic acids**: formic, m.; acetic, s.; chloracetic, v.s.; dichloracetic, v.s.; trichloracetic, v.s.; bromacetic, v.s.; dibromacetic, v.s.; propionic, s.; α-bromopropionic, v.s.; β-bromopropionic, s.; normal butyric, s.; isobutyric, v.s.; valerianic, s.; capronic, s.; œnantholic, s.s.; caprylic, s.s.; caprinic, s.s.; pelargonic, n.s.; myristinic, n.s.; palmitic, n.s.; margaric, n.s.; and stearic, n.s. **Dibasic acids**: oxalic, n.s.; malonic, n.s.; succinic, n.s.; pyrotartaric, n.s.; diacetylsuccinic, v.s.; and dibromosuccinic, s.s. **Esters**: ethyl formate, m.; amyl formate, m.; acotoacetic, m.; propyl acotate, m.; isobutyl acetato, m.; amyl acetate, v.s.; capryl acetate, s.s.; methyl propionate, m.; propyl propionate, v.s.; amyl propionate, s.; methyl butyrate, m.; ethyl butyrate, m.;

amyl butyrate, s.s.; isobutyl butyrate, s.; ethyl valeriate, v.s.; amyl valeriate, s.s.; isobutyl valeriate, s.; ethyl caprylate, s.s.; ethyl pelargonate, s.s.; ethyl oxalate, n.s., forming oxamide; ethyl malonate, m.; ethyl succinate, m.; ethyl lactate, m.; ethyl tartrate, m.; ethyl citrate, m.; ethyl carbonate, m.; tributyrine, m.; and amyl nitrite, s. **Cyanogen compounds:** methyl and ethyl cyanides, m.; cyanuric acid, s.; ethyl thiocyanate, m.; ethyl isothiocyanate, v.s.; and paracyanogen, n.s. **Amines:** methyl, m.; trimethyl, m.; diethyl, s.; dipropyl, s.; amyl, m.; diamyl, s.s.; tetramethylammonium chloride, s.s.; tetramethylammonium hydroxide, s.s.; tetramethylammonium iodide, s.s.; and hydroxylamine chloride, v.s. **Amido-acids:** glycine, amidopropionic acid, leucine, sarcosine (methyl glycerol), and tryosine, v.s. **Acetamide and ureides:** formamide and acetamide, v.s.; dichloroacetamide, cyanacetamide, thioacetamide, phenylacetamide and propionamide, v.s.; oxamide, s.s.; succinamide, s.s.; asparagin, creatine, and urea, s.; urea nitrate, thiourea, alkyl thiourea, urethane, allylthiourethane, and sulphocarbanilide, v.s.; uric acid, s. (n.s.); guanidine nitrate, v.s.; theobromine, alloxantine, parabanic acid, and dialuric acid, s.; uranil, v.s.; murexide, s.; and alloxan, v.s. **Hydroxy-acids:** glycolic acid, v.s.; lactic acids, v.s.; malonic, acid, s.s.; tartaric acid, s.s.; citric acid, s.s.; muconic acid, s.; and oxyisobutyric acid, v.s. **Sugars:** cane-sugar, v.s.; arabinose, s.; glucose, v.s.; fructose, v.s.; galactose, s.; phenylglucosazone, lactose, maltose, and raffinose, v.s. **Ethylene derivatives:** amylene, n.m.; allyl alcohol, m.; allyl isothiocyanate, m.; oleic acid, n.s.; maleinic acid, n.s.; fumaric acid, n.s.; citraconic acid, s.s.; itaconic acid, n.s.; mesaconic acid, s.s.; aconitic acid, s.; and crotonic acid, s.

Aromatic compounds.—**Hydrocarbons:** benzene, s.; toluene, s.s.; *o*-xylene, *m*-xylene, *p*-xylene, and ethylbenzene, s.s.; mesitylene, n.s.; cumene, pseudocumene, cymene, diphenylmethane, and triphenylmethane, n.s.; and diphenyl, s.s. **Halides:** chlorobenzene, bromobenzene, iodobenzene, hexachlorobenzene, dibromobenzene, and *p*-chlorotoluene, s.s. **Nitro-compounds:** nitrobenzene, v.s.; dinitrobenzene, s.; *o*-nitrotoluene, s.; *p*-nitrotoluene, s.s.; 1–2–4-trinitrotoluene, s.s.; trinitrotoluene, s.; *m*- and *p*-nitrochlorobenzene, s.s.; and *m*-nitro-*p*-chlorotoluene, s. **Amido-compounds:** aniline, *m*; *o*-toluidine, m.; *p*-toluidine, v.s.; *m*-nitro-*p*-toluidine, v.s.; asymmetric *m*-xylidine, s.s.; dimethyl- and diethyl-aniline, s.s.; methyldiphenylamine, s.s.; *m*- and *p*-nitraniline, v.s.; and picramide, v.s. **Phenols:** phenol, v.s.; *o*-, *m*-, and *p*-cresol, m.; pyrocatechol, resorcinol, hydroquinone, pyrogallol, orcin, and thymol, v.s.; guaiacol, anisol, and phenetol, m.; and menthol, s. **Substituted phenols:** *o*-, *p*-, 1–2–4-, and tri-nitrophenol, v.s.; *p*-nitroanisol, s.s.; eugenol, s.; anethol or phenethol, s.s.; and *o*- and *p*-amidophenol, v.s. **Alcohols, ethers, and aldehydes:** benzyl and cinnamic alcohols, m.; benzylethyl ether, s.s.; benzaldehyde, v.s.; anisaldehyde, m.; *m*-nitrobenzaldehyde, v.s.; cinnamic aldehyde, m.; vanillin, v.s.; and heliotropine, v.s. **Monobasic acids:** benzoic, benzoic anhydride, and *o*- and *m*-toluic, v.s.; *p*-toluic, s.; cinnamic, s.; *m*-bromobenzoic, v.s.; *o*- and *m*-nitrobenzoic, s.; *p*-benzoic, s.s.; *o*-, *m*-, and *p*-amidobenzoic, v.s.; *o*- and *m*-oxybenzoic, s.s.; *p*-oxybenzoic, s.s.; *o*-nitrocinnamic, v.s.; and nitrophenylpropiolic, gallic, anisic, and cumaric, s. **Diabasic acids:** *o*- and *p*-phthalic acid, s.s.; and phthalimide, v.s. **Esters:** methyl benzoate, m.; ethyl benzoate, v.s.; isobutyl benzoate, and amyl benzoate, n.s.; methyl salicylate, s.; phenyl and benzyl cyanides, m.; *p*-tolyl cyanide, v.s.; phenyl acetate, m.; phenyl salicylate, s.s.; phenyl isosulphocyanate, s.; and ethylphenyl urea, v.s. **Sulphoacids:** benzene sulphochloride, reacts; *o*-amidobenzene sulphonic acid, v.s.; *m*- and *p*-amidobenzenesulphonic acids, v.s.; benzosulphinic acid, and saccharine, s. **Acid amides and acid anilides:** formanilide, and acetanilide, v.s.; *p*-acetotoluidine, s.s.; benzamide, and *p*-chlorobenzamide, v.s.; benzanilide, s.s.; hippuric acid, v.s.; benzoylsulphamide, v.s.; *m*- and *p*-methoxybenzenesulphamide, and toluenesulphamide, v.s.; and carbazol, s. **Naphthalenes:** naphthalene, s.s.; α-naphthol, s.; β-naphthol, s.s.; α-naphthylamine, v.s.; β-naphthylamine, s.; nitro-β-naphthol, s.; and acetonaphthylamine, s.s. **Pyridine and quinoline:** pyridine, picoline, and collidine, m.; nicotine, s.; quinoline, m.; isoquinoline, s.s.; and dihydrocollidine dicarbonate, s.s. **Terpenes:** terebene, n.s.; carvene, and carvol, s.s.; pinene, sylvestrene, and turpentine, n.s.; borneo camphor, s.; and camphoric acid, n.s. **Miscellaneous:** acetophenone, and alizarin, s.; amygdaline, v.s.; anthracene and anthraquinone, n.s.; gun-cotton (s.s.); benzil, s.; benzoin, n.s.; brucine, s.; quinine hypophosphite, s., iodide, n.s., and sulphate, n.s.; quinone, and chloranil, s.; cholesterin, n.s.; cinchonin, n.s.; cinchonidine, s.s.; cocaine, n.s.; cocaine chloride, s.; codein, s.; codein nitrate, n.s.; cubebin, v.s.; digitalin, v.s.; fish-glue, syrupy; gum arabic, s.; guttapercha, reacts; hæmoglobin, s.s.; hæmatoxyline, s.; indigo (s.s.); camphor (v.s.); copal resin (s.s.); meconine, morphine, and narcotine, n.s.; phenanthrene, n.s.; phloridizine, and β-phthaldiadoxime, v.s.; piperidine, s.s.; piperine, n.s.; salicine, v.s.; santonine, n.s.; silk, n.s.; starch, swells; strychnine, acetate, bromide, and chloride, n.s.; tannin, s.s.; and theine, s.s.

F. de Carli obtained the following results for the solubilities of various organic compounds in liquid ammonia: *Benzene*, s.s., colourless; *toluene*, s.s., colourless; *ethyl benzene*, n.s., colourless; *nitrobenzene*, 24 per cent., yellow; *cumene*, s.s., yellow; *propylbenzene*, n.s.; *m-xylene*, s.s., colourless; *dinitrobenzene*, 19 per cent., red; *p-nitrochlorobenzene*, s.s., violet; *p-dibromobenzene*, n.s.; *o-nitrobenzene*, s.s., carmine; *cimene*, s.s., yellow ; *mesitylene*, s.s., colourless ; *dinitrotoluene*, s.s., blue ; *pseudocumene*, s.s., yellow ; *butylbenzene* (*tert.*), n.s. ; *hexachlorobenzene*, n.s. ; *m-dimethylcyclohexane*, n.s. ; *naphthalene*, n.s. ; *α-nitronaphthalene*, s.s., red ; *tetrahydronaphthalene*, n.s. ; *decahydronaphthalene*, n.s. ; *fluorene*, n.s. ; *anthracene*, n.s. ; *phenanthrene*, n.s. ; *dibenzil*, n.s. ; *stilbene*, s.s., colourless ; *diphenylmethene*, n.s. ; *triphenylmethane*, n.s. ; *acetanaphthene*, n.s. ; *benzyl alcohol*, m., colourless ; *menthol*, 16 per cent., colourless ; *benzoic aldehyde*, 82 per cent., yellow ; *salicylic aldehyde*, s.s., yellow ; *anisic aldehyde*, 70 per cent., yellow ; *cinnamic aldehyde*, s.s., yellow *cuminic aldehyde*, s.s., yellow ; *acetophenone*, s.s., colourless ; *benzylacetone*, s.s., yellow ; *phenic acid*, m., yellow ; *benzoic acid*, 46 per cent., colourless ; *salicylic acid*, m., colourless ; *o-nitrobenzoic acid*, 38 per cent., orange ; *sulphanilic acid*, 28 per cent., yellow ; *phthalic acid*, n.s. ; *picric acid*, 52 per cent., red ; *tetrachlorophthalic acid*, n.s. ; *cinnamic acid*, 6 per cent., yellow ; *benzyl acetate*, m., yellow ; *amyl salicylate*, s.s., colourless ; *ethyl cinnamate*, s.s., yellow ; *benzonitrile*, m., yellow ; *benzamide*, 35 per cent., yellow ; *p-toluidine*, 41 per cent., yellow ; *o-nitraniline*, 15 per cent., red ; *acetanilide*, 48 per cent., yellow ; *p-nitroanilide*, 10 per cent., yellow ; *benzilidenaniline*, n.s. ; *camphor bromide*, n.s. ; *pinene*, s.s., colourless ; *carvene*, n.s. ; *dimethylpyrone*, n.s. ; *phenylpyrrole*, n.s. ; *carbazole*, s.s., yellow ; *acridine*, s.s., yellow ; *thiodiphenylamine*, s.s., green ; *antipyrine*, n.s. ; *amylene*, n.s. ; *caprylene*, n.s. ; *hexadecilene*, n.s. ; *malic acid*, n.s. ; *maleic acid*, n.s. ; *fumaric acid*, n.s. ; *oleic acid*, n.s. ; *palmitic acid*, n.s. ; *stearic acid*, n.s. ; *aconitic acid*, n.s. ; *thiourea*, 37 per cent., colourless ; *guanidinium carbonate*, n.s.

H. Stamm also measured the solubilities of the salts of the alkalies in liquid ammonia —potassium hydroxide, nitrate, sulphate, chromate, oxalate, perchlorate, persulphate, chloride, bromide, iodide, carbonate, and chlorate : rubidium chloride, bromide, and sulphate ; cæsium chloride, iodide, carbonate, and sulphate ; lithium chloride and sulphate ; sodium phosphate, phosphite, hypophosphite, fluoride, chloride, iodide, bromate, perchlorate, periodate, hyponitrite, nitrite, nitrate, azide, dithionate, chromate, carbonate, oxalate, benzoate, phthalate, isophthalate ; ammonium, chloride, chlorate, bromide, iodide, perchlorate, sulphate, sulphite, chromate, molybdate, nitrate, dithionate, thiosulphate, persulphate, thiocyanate, phosphate, phosphite, hypophosphite, arsenate, arsenite, amidosulphonate, ferrocyanide, carbonate, benzoate, methionate, phenylacetate, picrate, salicylate, phenylpropionate, benzoldisulphonate, benzolsulphonate, phthalate, trimesinate, mellitate, aliphatic dicarboxylates, tartrate, fumarate, and maleinate ; and phenol.

§ 18. The Chemical Properties of Ammonia

Ammonia has a pungent, exciting odour ; animals die when submerged in the gas. When inhaled, the vapour irritates the nose and air-passages, causing a pungent sensation and sneezing. The eyes and nose water, and the pulse and respiration are accelerated. Ammonia causes a rise of blood-pressure, and stimulates the heart. M. von Pettenkofer [1] said that air laden with ammonia causes pneumonia —0·3 per cent. (in air) is dangerous, and 0·5 per cent. to those accustomed to it. According to J. Muck, and E. Hallervorden, small doses of ammonia act as a nerve stimulant. Conc. aq. ammonia reddens the skin, and with prolonged contact, it may produce a blister. If ammonia be introduced with the food, the urea discharge is augmented. P. P. Dehérain showed that small quantities have a toxic action on some plants ; while A. Müntz showed that ammonia can be assimilated by the nitric ferments. P. Mazé has studied this subject. Ammonia plays an important part in the physiology of plants, for it is converted by the nitric ferment—*vide supra*— into nitrates which are necessary food-stuffs. P. N. Prianichnikoff reported that in the higher plants ammonia plays an important part as the starting-point for the

synthesis of protein and as an end-product in the oxidation of nitrogenous substances. It does not, however, accumulate as such, but is converted into asparagine. Plants may be divided into three types according to the facility with which they accomplish this synthesis of asparagine: (i) Plants which readily absorb ammonia from soln. and convert it into asparagine—*e.g. Hordeum sativum* (barley), *Zea mays* (maize), and *Cucurbita pepo* (pumpkin). (ii) Plants in which the absorption of ammonia is very feeble and in which the presence of ammonia in the culture soln. retards the oxidation of nitrogenous substances. The absorption of ammonia can be increased by adding calcium carbonate to the culture soln.—*e.g. Pisum sativum* (pea) and *Vicia sativa* (vetch). (iii) Plants in which the presence of ammonia in the culture soln. prevents the conversion of ammonia into asparagine—*e.g.* the yellow lupin (*Lupinus luteus*). The addition of calcium carbonate has no effect in these cases.

A. Smits[2] drew attention to H. B. Baker's observations on the change in the properties which occurs when some gases are intensely dried. He assumes that two different kinds of molecules are concerned in every phase: $\alpha\text{-}NH_3 \rightleftharpoons \beta\text{-}NH_3$; one kind is active, the other inactive. With intense drying, the equilibrium is shifted to the inactive side so that intensely dried ammonia contains only inactive molecules. W. Kuhn found that ammonia gas in quartz vessels is decomposed completely by monochromatic light of wave-length 2025–2140 A. at a speed proportional to the energy absorbed. Aq. soln. of the gas undergo no decomposition. The number of quanta absorbed by a mol of ammonia undergoing decomposition, varies from 2 to 2·5, and is independent of the press. (900 to 5 mm.). For temp. of 10°–20°, the speed of decomposition is independent of temp., and, generally, this speed is not affected by the size of the quartz surfaces (whereas the thermal dissociation is accelerated by quartz surfaces). The speed of decomposition is also unaffected by the addition of metallic sodium, and is therefore independent of the action of minute traces of water. With monochromatic light of $\lambda=2063$, the number of quanta necessary to decompose a mol of ammonia is 3·4, or as many as 10 if the monochromatization is very perfect. From the heats of dissociation for $N_2=N+N(-140,000$ cals.), $H_2=H+H(-84,000$ cals.), and $NH_3=0{\cdot}5N_2+1{\cdot}5H_2(-11,000$ cals.), whence $NH_3=N+H_2+H-123,000$ cals., and $NH_3=N+H+H+H-207,000$ cals., it follows that a quantum $h\nu$ for the ray 2063 corresponds with 128,000 cals. per mol. The energy furnished by the absorption of a quantum suffices for the first, but not for the second change. On these lines may be explained the facts that several quanta are required to decompose a mol of ammonia, and that the speed of decomposition depends on the degree of the monochromatization of the ultra-violet radiation. E. Warburg, A. Coehn and G. Prigent, E. Regener, and M. Berthelot and H. Gaudechon studied the photochemical decomposition of ammonia—*vide supra*. R. G. Dickinson and A. C. G. Mitchell, and H. S. Taylor and J. R. Bates studied the decomposition of ammonia by optically excited mercury atoms. C. Matignon concluded that some ammonia in the higher regions of the atmosphere is decomposed into its elements by the action of the ultra-violet light. E. Wourtzel observed that α-rays from radium decompose ammonia gas.

E. C. C. Baly and H. M. Duncan studied the decomposition of ammonia by means of a hot platinum wire. Two types of ammonia may be prepared—an inactive and an active modification—which are decomposed to different extents by the same quantity of energy. The active form is obtained by the slow withdrawal of ammonia from a cylinder containing the compressed gas; by warming the conc. aq. soln. and drying the gas by quicklime; and by isothermal evaporation of the liquefied gas at its b.p. The inactive form is obtained by the rapid evaporation of the liquefied gas. The inactive gas slowly recovers its activity on remaining in contact with the liquefied gas. The same effect can be produced by gently warming the gas by means of a platinum wire heated at 200°. In order to observe these phenomena, the platinum wire must be activated in the same way as is customary in W. Ostwald's process for the catalytic oxidation of ammonia in air to nitric acid. Alternatively, the activation may be effected by rapidly heating and cooling the wire for several hours. Active and inactive ammonia, passed alternately into the same decomposition vessel, give with a fixed supply of energy high and low decomposition values. When the same sample of ammonia is twice exposed to the heated wire, the ratios of the amounts decomposed in the two cases differ very materially with the two forms. The addition of water vap. increases the reactivity of ammonia, the increase being proportional to the amount of water vap. present. The enhanced reactivity is removed on drying the gas with quicklime. To summarize, the active and inactive forms of ammonia differ in the relative amounts of energy required for their decomposition. The phase of lower energy content is identical with that which is obtained when ammonia is completely freed from moisture, and it does not combine with hydrogen chloride. R. E. Burk found that the decomposition of ammonia on the surface of a heated molybdenum wire is of zero order. The presence of hydrogen produces a slight accelerating effect, whilst that of nitrogen produces a marked retardation, the velocity after first decreasing with increasing conc. of nitrogen attaining a final limiting value. The film of nitrogen on the surface of the wire is very persistent and is not removed by pumping off in vacuo. Wires, however, return to normal activity after performing one or more experiments with ammonia. Activated mols. only of nitrogen condense to form the poisoning film, which may consist of atomic nitrogen. Since the rate of reaction is not zero at nitrogen press. which are so great that the surface is almost completely covered, the reaction must still proceed on parts of the surface which are not poisoned or, at a reduced rate, on a film of nitrogen. The two possible mechanisms cannot be distinguished since both yield the same type of formula for the velocity of the reaction. At temp. between 1097° K. and 1228° K., the logarithm of the half-life varies linearly with the reciprocal of the absolute temp., the slope of the line corresponding with a heat of activation of 53,200 cals. This is a true heat of activation.

The decomposition of ammonia by heat, and the electrical discharge has already been discussed in connection with the synthesis of that gas. E. Regener found that ammonia is decomposed by ultra-violet light. **Hydrogen** has no action on ammonia or on its aq. soln. E. Böhm and K. F. Bonhöffer found that active hydrogen had no action on ammonia. A. T. Larson and C. A. Black measured the solubility of hydrogen in liquid ammonia between —25·2° and 22·0°, and 50–150 atm. press. According to J. J. Berzelius, ammonia is feebly combustible in **air**, for it burns with a pale yellow flame when in immediate contact with the flame of a candle, but the combustion does not continue without the extraneous flame. The gas does not support combustion in the ordinary sense of that term. N. R. Dhar and R. P. Sanyal found that when air or oxygen is passed into soln. of ammonia exposed to tropical sunlight, nitrites are formed ; and a mixture of ammonia and oxygen forms nitrogen. K. A. Hofmann and co-workers found that the oxidation of ammonia to nitrate by air proceeds readily at 380°–400° in the presence of a basic contact agent such as soda-lime and can be accelerated in an unusual degree by increase of pressure. Copper carbonate, nickel powder, silver powder, and nickel carbonate accelerate the reaction in order of increasing efficiency. Soda-lime may be replaced by the oxides or carbonates of the alkaline earths, provided that the maximum temp. does not exceed the temp. of decomposition of the corresponding nitrate. Technical nitrolim is readily nitrified at temp. below 200° if mixed with soda-lime and copper oxide and exposed in thin layers to the air during several days. In all the cases of oxidation of nitrogen described above, the presence of nitrite can be readily detected at the commencement of the action, particularly when oxidation takes place rapidly. Towards the end of the change, when the nitrate formation has attained its maximum, the nitrite content diminishes. The tervalent nitrogen of ammonia or its derivatives passes therefore into the tervalent oxidized condition in the nitrite, which, under the conditions of the experiments, is invariably oxidized to nitrate with considerable rapidity. G. Kassner obtained nitric acid by oxidizing ammonia by oxygen in the presence of a heated catalyst containing lead, manganese, alkaline earths, and oxygen.

M. Berthelot and H. Gaudechon observed that under the influence of ultra-violet rays a mixture of ammonia and oxygen forms water and nitrogen. Ammonia burns in oxygen, forming nitrogen, water, a small proportion of ammonium nitrate, and a trace of nitrogen peroxide. H. B. Jones found that nitric acid is formed during the combustion of an alcoholic soln. of ammonia. A. W. Hofmann showed that if ammonia be mixed with oxygen, say, by bubbling a stream of oxygen through a small quantity of a conc. soln. of ammonia warmed in a flask, the gas issuing from the flask can be ignited; it burns with a greenish-yellow flame. In a few moments the soln. in the flask will be too dilute to show the flame. The experiment has been modified in various ways by W. Heintz, I. P. Ossipoff, M. Rosenfeld, A. Valentini, H. Schulze, D. L. Hammick, F. Brandstätter, S. Lupton, O. Wehrheim, W. R. Hodgkinson and F. K. Lowndes, and A. Klages. By sending a jet of ammonia into the air-holes of a Bunsen's burner, the flame will be found to expand, and acquire a yellow tinge. The effect is shown better by delivering a jet of ammonia into the centre of the tube of a Bunsen's burner. If a stream of oxygen be sent into a cylinder, and a stream of ammonia be sent into the same cylinder through a wide glass tube, the ammonia can be ignited, and it will burn with a yellowish flame. The analysis of the gases in A. Smithell's flame separator shows that the yellow part of the flame is an effect of undecomposed ammonia, and not an effect of the union of nitrogen and oxygen. He also found that with the mixture of hydrogen and nitrogen, obtained by passing ammonia through a hot tube, in the first cone of the flame, the whole of the oxygen combines with hydrogen to form steam, which, with the nitrogen and excess of hydrogen, passes to the top of the outer tube, where this hydrogen burns with the outside air in a second flame. J. M. Eder examined the spectrum of ammonia burning in oxygen gas.

According to A. B. de Fourcroy, a mixture of two vols. of ammonia and one to six vols. of oxygen explodes when sparked; and when a mixture of ammonia and an excess of oxygen is passed through a red-hot tube, nitric acid is formed. G. B. Taylor represented the heat of the reaction: $4NH_3+5O_2=4NO+6H_2O+214,200$ cals., and $4NH_3+3O_2=2N_2+6H_2O+300,600$ cals.; and the rise of temp., $\theta=(75150x-2{\cdot}600y)(7{\cdot}08+3{\cdot}41x-0{\cdot}25y+8{\cdot}34V/B-V)$, where V denotes the partial press. of water-vapour; B, the total press. of the mixture of air, ammonia, and water-vapour; x, the mol. fraction of ammonia in the mixture; and y, the mol. fraction of nitric oxide produced in the oxidation.

F. Kuhlmann observed that a little nitric oxide and nitrogen peroxide are formed when a mixture of air and ammonia is passed through a red-hot tube. W. Henry showed that the flame of a burning substance is enlarged when the air is mixed with ammonia; and he was not able to make a mixture of air and ammonia which would detonate with the electric spark. H. Schlumberger and H. Piotrowsky said that mixtures of 16·5 to 26·8 per cent. by vol. of ammonia are explosive, and A. Reis found that the limits for the propagation of flame in ammonia-oxygen mixtures are below 15 and above 80 per cent. by vol. of ammonia. A. G. White found that in a tube 5 cms. in diameter, the ranges throughout which ammonia-air and ammonia-oxygen mixtures propagate flame, in vol. percentages of ammonia, are:

		Upwards.	Horizontal.	Downwards.
NH_3–Air	18°	16·1–26·6	18·2–25·5	none
	140°	16·0–28·7	17·0–27·5	19·9–26·3
	250°	14·0–30·4	15·9–29·6	17·8–28·2
	450°	12·3–33·9	13·5–33·1	14·4–32·0
NH_3–O_2	18°	15·3–79·0	16·7–79·0	18·1–79·0
	250°	—	14·8–79·0	15·8–79·0
	450°	—	12·6–79·0	13·5–79·0

A. G. White also calculated the flame temp. which ranged from 1610° to 1840°. He also studied the propagation of flame in mixtures of hydrogen and ammonia.

W. P. Jorissen studied the explosive limits of mixtures of ammonia, hydrogen, and air or oxygen; and represented the results by the triangular diagram, Figs. 37 and 38. J. R. Partington and A. J. Prince exploded mixtures of dry electrolytic gas and ammonia at 85° and 380 mm. press. so that no steam condensed. The mixture becomes explosive when the ratio of electrolytic gas to ammonia is just over unity, when 79 per cent. of the ammonia is decomposed. When the ratio is just above 3, the decomposition is complete, the sole products being steam, hydrogen, and nitrogen. When ammonia is exploded with a deficiency of oxygen, the excess of ammonia is completely decomposed into nitrogen and hydrogen, and oxides of nitrogen are formed only if the ratio of ammonia to oxygen is less that 1·6; the maximum oxidation of nitrogen is 16 per cent. with the ratio 1·22. The commencement of oxidation of nitrogen is marked by colour changes in the flame, which changes from yellow to green, violet, and white as the oxidation of nitrogen increases. When ammonia is exploded with oxygen, the amount of nitrogen oxidized is greater than in the explosion of a corresponding mixture of nitrogen, hydrogen, and oxygen. I. W. Cederberg studied the conditions for the catalytic combustion of explosive mixtures of ammonia and oxygen.

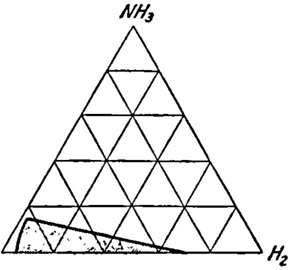

FIG. 37.—Explosive Limits in the System: H_2–NH_3–Air.

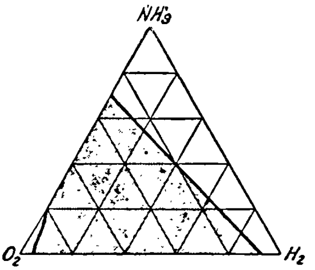

FIG. 38.—Explosive Limits in the System: H_2–NH_3–O_3.

J. W. Döbereiner found that platinum-sponge has no appreciable action on a mixture of equal vols. of ammonia and oxygen, but if the ammonia be mixed with electrolytic gas, the latter warms up the platinum and the ammonia is oxidized; W. Henry found that the mixture of equal vols. of ammonia and oxygen reacts in the presence of spongy platinum at 193°; F. Kuhlmann, in 1839, that the oxidation of ammonia occurs at about 300°, and that platinum-black is less efficient than spongy platinum; and C. F. Schönbein, that a heated platinum wire spiral in air charged with ammonia produces a white cloud of ammonium nitrate. D. Meneghini observed no action with a platinum spiral at 350°, but the reaction is vigorous between 400° and 450°. In K. Kraut's experiment, a stream of oxygen is sent through a conc. soln. of ammonia in a beaker in which is suspended a spiral of thin ($\frac{1}{4}$ mm.) platinum wire (recently ignited). If the current of oxygen be very slow, the platinum wire will glow red-hot, and the beaker will soon be filled with reddish-brown fumes of nitrogen peroxide. If the current of oxygen be faster, a small explosion will occur every now and again: the first explosion will be stronger than the second, the second stronger than the third, etc., and the soln. in the beaker will be found to contain both ammonium nitrite and nitrate. H. N. Warren used platinized ashes at a red-heat as a catalytic agent for the oxidation of ammonia, and the yields of nitrogen oxides with this catalyst were investigated by W. Reinders and A. Cats; O. Schmidt and R. Böcker—who, at a red-heat, obtained a 75 per cent. yield of oxides of nitrogen; and B. Neumann and H. Rose—who obtained a 96 per cent. yield at 500°. E. K. Rideal and H. S. Taylor found that during the action, the platinum swells up into microscopic efflorescences probably owing to the soln. of the gas and its subsequent expulsion. C. Schick employed platinized glazed-pottery, and this was said to have a longer life than platinum sponge. The subject was also discussed by M. Taliani, V. I. and N. A. Maliarewsky, L. Andrussoff, P. Pascal and E. Decarrière, H. A. Curtis, J. Baumann, W. S. Landis, A. A. Campbell, B. Neumann and H. Rose, and L. Cambi. E. Decarrière studied the catalytic action of palladium. P. Wenger and C. Urfer found that in the oxidation of ammonia, 97 per cent. is converted into nitric and nitrous acids by platinum-black as catalyst at 533°–562°; whilst with rhodium-black, a 69·7 per cent. oxidation is attained at 662°. L. Duparc and co-workers found rhodium more effective than platinum as catalyst.

W. Ostwald used corrugated platinum foil as catalyst, and he found that if the gas is not passed over the catalyst rapidly, ammonia is oxidized to nitrogen, $4NH_3+3O_2=2N_2+6H_2O$, but by taking suitable precautions, the ammonia can be oxidized to nitric oxide: $4NH_3+5O_2=4NO+6H_2O$. The heat of the nitric oxide reaction is 220 Cals., at ordinary temp., and is practically constant at 53 Cals. between 500° and 700°. The nitric oxide can be converted into nitric acid in the usual way—*vide infra*. At low temp., little or no nitric oxide is formed, but as the temp. rises, the rate of oxidation increases, reaching a maximum at about 750°, as indicated in Fig. 39. Beyond 750°, the ammonia decomposes into its constituents. F. C. Ziesberg described W. Ostwald's process. The reaction has been studied by F. G. Liljenroth, who showed that the heat of the exothermic reaction is sufficient to raise the temp. of the moving gas-mixture to 675° at the catalyst. If the initial temp. be 25°, the temp. of the catalyst will be raised to 700°. The smaller the percentage of ammonia oxidized, the smaller will be the heat developed during the reaction, and the lower the temp. of the catalyst. E. B. Andersen investigated the relation between the yield of oxide and the temp. and rate of flow of the gases.

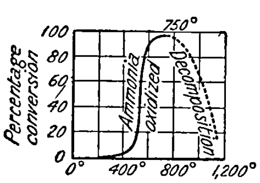

FIG. 39.—The Effect of Temperature on the Oxidation of Ammonia with Platinum as Catalytic Agent.

D. I. Mendeléeff supposed that an intermediate product, orthonitrous acid, $N(OH)_3$, is formed. Nitric oxide is the only compound which has been isolated in the oxidation of ammonia to nitrous or nitric acid. W. Reinders and A. Cats represented the reaction: $4NH_3+5O_2=4NO+6H_2O$, followed by $4NH_3+6NO=5N_2+6H_2O$; and $4NH_3+3O_2=2N_2+6H_2O$. The first reaction is accelerated by platinum or ferric oxide; the other reactions do not require a catalyst but are speeded up by glass or porcelain. F. Raschig does not accept the view that the combustion of ammonia in an excess of oxygen results in the formation of nitric oxide and water; and, if the ammonia is in excess, he writes: $4NH_3+3O_2=2N_2+6H_2O$. F. C. G. Müller found that under these conditions, the gaseous product contained 59 per cent. nitrogen and 41 per cent. hydrogen, and assumed that a portion of the ammonia dissociates into its constituent elements at the high temp. of the flame. If this were so, hydrogen ought also to be formed when oxygen is in excess, whereas under these conditions, 90 per cent. and more nitric acid is formed; nor is the ratio altered by cooling the flame. F. Raschig suggested that some hypothetical diimide is formed when the ammonia is in excess—$2NH_3+O_2=N_2H_2+2H_2O$—which would probably dissociate into hydrogen and nitrogen, and part of the ammonia may burn according to $4NH_3+3O_2=2N_2+6H_2O$, or else with the intermediate formation of hydrazine—$4NH_3+O_2=2N_2H_4+2H_2O$—which subsequently decomposes into nitrogen and hydrogen. F. Raschig proved that some hydrazine is actually formed when oxygen burns in ammonia. He therefore concluded that the main reaction in the combustion is $2NH_3+O_2=N_2H_2+2H_2O$, with the side reaction $4NH_3+O_2=2N_2H_4+2H_2O$. F. C. G. Müller found that the products of combustion of ammonia in oxygen contain hydrogen and nitrogen in the ratio 2 : 3; and this result is not altered by cooling the flame with cold water. Hence, it cannot be due to the dissociation of ammonia. F. Raschig's assumption that the equation $2NH_3+O_2=N_2H_2+2H_2O$ followed by the instantaneous dissociation of the diimide and partial combustion of the hydrogen does not account for the proportion of hydrogen produced. L. Andrussoff suggested that the group, NON, is an intermediate product, but J. R. Partington objected that if so, nitrous oxide might be expected as a by-product of the oxidation. This has not been found. E. Bodenstein assumed that the primary change involves the formation of nitrotyl: $NH_3+O_2=H_2O+HNO$, which is then converted, by oxygen, into nitric acid and then into nitric oxide, water and oxygen, or else, by ammonia, into nitrogen, water, and hydrogen. In the absence of oxygen or ammonia, the nitrotyl may form (*a*) nitrous oxide and water; (*b*) nitrogen, oxygen, and water; or (*c*) hydrogen and nitric oxide. J. Zawadzky and co-workers hold that the first step in the oxidation of ammonia is the dissociation of that compound into its constituent elements; atomic nitrogen then combines with oxygen to form nitric oxide, provided the temp. is not too high to allow the existence of this compound; otherwise the reaction $N+N=N_2$ will proceed at the expense of the reaction $N+O=NO$, and it is on the relative rates of these two reactions that the yield of the desired product depends. They do not agree with B. Neumann and H. Rose that the formation of nitrogen at a high temp. is due to the direct oxidation of ammonia to nitrogen and water, because in that case the reaction should be independent of the rate of flow of the gases and show a definite optimum temp., whereas equally good results can be obtained with higher temp. than the 500° used by B. Neumann and H. Rose, provided the rate of flow is suitably accelerated. Nitric oxide decomposes quite appreciably (12·2 per cent.) at 800°, and this decomposition is greatly assisted by contact with a platinum catalyst. The reason of the poor yields at temp. below 500° may be attributed to the reaction between ammonia and nitrogen trioxide and peroxide, whilst at higher temp. these oxides dissociate into oxygen and nitric oxide. According to Shun-Ichi Uchida, the catalytic oxidation of ammonia, $4NH_3+3O_2=2N_2+6H_2O$, occurs simultaneously with $4NH_3+5O_2=4NO+6H_2O$; he assumes, however, that the ammonia oxidizes to nitric oxide, which then, by a consecutive reaction decomposes by two concurrent reactions, $4NH_3+6NO=5N_2+6H_2O$, and $2NO=N_2+O_2$. The first of these reactions was shown by G. P. Baxter and C. H. Hickey to be very slow even in the presence of catalysts. When a stream of ammonia and air is passed at different speeds about a thin layer of a catalyst at a constant temp. the yield of nitric acid plotted against the time of contact with the catalyst yields a maximum. Shun-Ichi Uchida showed that the maximum can be explained by assuming that the resultant reaction involves the consecutive changes: $4NH_3+5O_2=4NO+6H_2O$ followed by $2NO=N_2+O_2$, and that the catalyst accelerates the two reactions at different rates. K. Jellinek, E. K. Rideal, and W. W. Scott discussed this second reaction as a source of loss in the oxidation of ammonia to nitric oxide. If the two reactions are unimolecular with the constant k_1 with respect to ammonia, and k_2 with respect to nitric oxide, the yield of nitric oxide C, at the time t, can be represented by $C=k_1(k_2-k_1)^{-1}(e^{-k_1t}-e^{-k_2t})$. With platinum gauze as catalyst, $k_1=5725$ per sec., and $k_2=31{\cdot}4$ per sec.; and with iron-bismuth as catalyst, $k_1=204{\cdot}5$ per sec., and $k_2=1{\cdot}17$ per sec. The maximum yield is then $C_m=(k_1/k_2)^{k_2/(k_2-k_1)}$ which is in agreement with observations. J. Baumann supposed the two reactions to be: $4NH_3+5O_2=4NO+6H_2O$, and $2NH_3+3O=N_2+3H_2O$; and S. Uchida, the rapid change $4NH_3+5O_2=4NO+6H_2O$, followed by the slow change $2NO=O_2+N_2$. The velocity constant for the first reaction is 180 times as large as that for the second.

Several industrial works have used the process of oxidation with the platinum plug as catalyst. A. Frank and N. Caro, G. Schäphaus, A. A. Campbell, and W. S. Landis have described the use of a single layer of electrically heated platinum gauze as catalyst for the oxidation of ammonia. K. Kaiser proposed the use of several superposed fine platinum or iridium gauzes in close contact, and preheating the gases at 300°–400° before passing to the catalyst so as to enable a rapid stream of gas to be passed through the system. J. R. Partington used two gauzes separated by narrow silica rods. The subject has been discussed by G. A. Perley,

E. Schlumberger, C. S. Imison and W. Russell, C. L. Parsons, and L. C. Jones. With platinum foil (W. Ostwald) and regenerative heating, J. R. Partington obtained a conversion efficiency of 90–95 per cent., and an output of 1·7 to 2·0 kgrms. of nitric acid per gram of platinum per 24 hrs.; with a single platinum gauze (A. Frank and N. Caro) and electrical heating, the respective numbers were 90–93 per cent. and 11 kgrms.; with four superposed platinum gauzes (K. Kaiser), 95 per cent. and 12 kgrms.; with two platinum gauzes slightly separated, with preheating of gases, 95 per cent. and 16 kgrms.; and with two platinum gauzes in contact, steam, and oxygen preheated to 500°–600°, 98–99 per cent. and 21 kgrms. The injurious effects of ammonia contaminated with phosphine, and acetylene have been discussed by C. L. Parsons, L. C. Jones, H. A. Curtis, and G. B. Taylor and J. H. Capps; 0·00002 per cent. of phosphine reduces the yield 30 per cent., and with 0·02 per cent. of phosphine the yield fell from 93·8 to 3·9 per cent. The presence of hydrogen sulphide counteracts the ill-effects of phosphine and of acetylene, but in general hydrogen sulphide has a baneful influence. E. Decarrière found that hydrogen to the extent of 0·44 per cent. has a slightly favourable influence, but with 1·0 to 1·5 per cent. it slightly reduces the activity of the catalyst; hydrogen phosphide reduces the activity 30 per cent., hydrogen sulphide partly neutralizes the baneful effect of hydrogen phosphide, and of acetylene. The subject was also studied by P. Pascal and E. Decarrière. Shun-Ichi Uchida found that the platinum catalyst evaporates slowly but distinctly at as low a temp. as 580°; this is not due to the scaling off of the activated surface. The loss of platinum was also observed by W. S. Landis.

A great many catalysts other than the preparations of platinum have been tried, but most have been found unsuitable—in some cases because of the small activity, in others because of rapid deteriorations; and in still others, an inconveniently high temp. may be required. In 1789, I. Milner found that ammonia is oxidized in contact with manganese dioxide, at a red-heat, producing nitrous acid and nitric oxide. Red-lead did not give this result, but ferrous sulphate which had been precalcined to whiteness gave better results. J. Black commenting on this result correctly explained the action in the following manner:

> The volatile alkali being a compound of hydrogen and azote, we need only suppose that part of it is totally decomposed and destroyed by the action of the oxygen contained in the manganese. Part of it, uniting with the hydrogen, forms water or watery vapour; and part, uniting with the azote, forms vapours of nitrous acid.

He also added that it was reported in the newspapers that " during the Napoleonic wars, the French chemists procured saltpetre for the army by blowing alkaline gas, and even putrid steams, through red-hot substances, like manganese dioxide, which readily yield oxygen." L. B. Guyton de Morveau, and L. N. Vauquelin oxidized ammonia to nitrates by passing it over hot manganese dioxide. C. S. Piggot studied the action of manganese dioxide alone and when mixed with copper or silver oxide, and also of silica and of various alloys of manganese, copper, silver, and iron. A mixture of manganese oxide with 40 per cent. of copper has a 90 per cent. efficiency at 800°. W. Manchot and J. Haas examined silver oxide intimately mixed with pumice as catalyst. H. G. Kreul used ferric oxide with 5 per cent. bismuth oxide as catalyst; and the General Chemical Co., an ignited mixture of aluminium and cobalt nitrates. The general subject was examined by M. Guichard. G. Kassner oxidized ammonia to nitric acid by means of a catalyst he called *nitroxan*, which is a compound or equimolar mixture of metaplumbate and manganate of barium, and is made by heating in air a mixture of barium orthoplumbate and manganese dioxide in the correct proportions. The reaction is probably as follows: $2BaPbO_3,BaMnO_4+NH_3=HNO_3+2BaPbO_2+2BaMnO_3+H_2O$; $BaPbO_2+BaMnO_3+O_2=BaPbO_3,BaMnO_4$. The nitric acid is retained as barium nitrate, which is adsorbed as such by the substance of the catalyst. When the reaction is carried out at 600°, *i.e.* above the decomposition temp. of barium nitrate, the products contain an excess of nitrogen peroxide, which, in the presence of oxygen and the water which is formed, is rapidly condensed to liquid nitric acid. Poor yields are obtained when the barium nitrate is formed at a low temp. (260°–450°), and is then decomposed by raising the temp.; the ammonia is never completely oxidized in the first part of the reaction and nitric oxide is formed which reacts with free ammonia with the formation of nitrogen, especially if any uncombined manganese dioxide is present in the catalyst. By lixiviating the barium nitrate from the catalyst and replacing the barium thus removed by finely-powdered barium hydroxide, better yields are obtained, the catalyst improving with use. In this way a 100 per cent. conversion of ammonia into nitric acid may be obtained. J. von Liebig found that the reaction is catalyzed by ferric oxide; and A. F. de Fourcroy, by mercuric oxide. The last-named called the reaction *une décomposition réciproque.* F. Kuhlmann found that copper hydroxide, copper, nickel, and iron are less active than platinum. R. Marston proposed copper as catalyst; E. Aubertin, chromic oxide and chromates; C. M. Tessié du Motay, manganates, permanganates, dichromates, and alkali plumbites; H. Schwarz, sodium manganate; L. C. Jones and co-workers, plumbites of aluminium, zinc, or cadmium; C. L. Parsons, lead oxide on bone-ash at 100°; A. Frank and N. Caro, ceria and thoria; B. Neumann and H. Rose, ferric oxide at 670°. K. Inaba studied a mixture of iron and bismuth oxides as catalyst, and the yield was increased in the presence of thoria. The Badische Anilin- und Soda-fabrik recommended oxides of the iron group; F. Bayer and Co., iron oxide, and promotors—cerium or bismuth oxides—at about 800°; that company also proposed iron oxide with bismuth oxide; iron oxide with tellurium; and platinum with lead. B. Neumann and H. Rose examined the effect of iron-bismuth oxide at 600°; D. Meneghini tried roasted pyrites, chromic oxide, or oxides of the rare earths—ferric, manganic, and ceric oxides were less active; W. Reinders and A. Cats compared platinized asbestos, or glass, copper wire, thorium oxide and pumice, ferric oxide on glass or asbestos, and oxidized iron-gauze. They found 80–90 per cent. oxidation with platinum, or ferric oxide. Ferric oxide worked best at 650°–700°; and platinized asbestos or glass, at 600°. N. Smith found that stannic and manganic oxides oxidize ammonia to nitrate and nitrite at ordinary temp.; ferric oxide and lead dioxide have but a slight action. Various oxides—copper, silver, vanadium, chromium, molybdenum, lead, manganese, cobalt, and nickel—have been tried. E. B. Maxted found that the percentage conversion with iron catalyst activated with the promotors copper, thorium, tungsten, cerium, or bismuth, at 700°, when the time of contact of the gas-mixture with the catalyst is 0·015 sec., is as follows, when iron alone gave 83·5 per cent. conversion:

	Fe(Mn)	Fe(Cu)	Fe(Th)	Fe(W)	Fe(Ce)	Fe(Bi)
Per cent. conversion	75·0	86·0	87·3	89·3	90·0	92·0

The relative efficiency with different rates of flow of the gas-mixture is illustrated by Fig. 40, where the speed of flow is expressed in litres per hour per c.c. of free space in the reaction chamber—calculated at room temp. Each c.c. of free space corresponds with 20 sq. cms. of catalyst surface. E. I. Orloff observed the oxidation of ammonia when mixed with air and passed over a heated copper gauze: $4NH_3+3O_2=2N_2+6H_2O$, with traces of nitrous and nitric acids—aniline, toluidine, and pyridine were oxidized in a similar way. W. W. Scott and W. D. Leech found that the conversion efficiency of cobalt oxide at 600°–800° is 79·3 per cent. This is augmented when about 3 per cent. of bismuth, or 10 to 12 per cent. of alumina, is used as promotor. The efficiency is then increased up to 90 per cent. Metals with m.p. below that of cobalt act as stimulants of the reaction, while metals with a higher m.p. retard the reaction. Observations on the subject were made by W. Kochmann, W. Moldenhauer and O. Wehrheim, H. Petersen, N. Busvold,

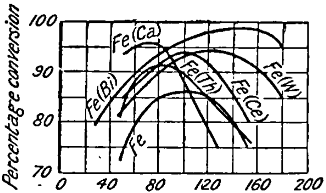

FIG. 40.—Efficiency of Catalysts in the Oxidation of Ammonia.

P. Wenger and C. Urfer. N. Smith found that in the oxidation of tin or copper in air, ammonia is simultaneously oxidized—induced reactions; zinc has no action, but in glass dishes positive results were sometimes obtained—while only a slight action was observed in the oxidation of ferrous and manganous hydroxides.

In practice, where nitric acid is made by the oxidation of ammonia, the catalyst employed may be a platinum plug (W. Ostwald); an electrically heated wire gauze (K. Kaiser); or iron activated by another metal. The most satisfactory catalyst is platinum gauze of fine mesh, or platinum foil whose smooth surface is roughened by a deposit of platinum-black. Platinum sponge, or platinum-black alone is much too active. A thin layer of catalyst gives the best results, because with a thick layer, or a low velocity, some nitric oxide is decomposed. The platinum gauze processes can be illustrated by A. Frank and N. Caro's reaction chamber. At the bottom, air enters on one side, ammonia on the other. Valves are provided so that the correct proportions can be regulated. The gases are mixed by a revolving aluminium fan and then pass through the heated platinum gauze. The gauze is electrically heated to 700°, but once the reaction commences, in some arrangements, the heat developed by the reaction suffices to keep the gauze red-hot. The lower half of the casing of the reaction chamber is cooled by water so as to prevent, as far as possible, the thermal decomposition of the ammonia by the heat radiated from the gauze. The combustion chamber is lined with aluminium so as to prevent any iron oxide from falling on the platinum gauze. The industrial oxidation of ammonia to nitric acid has been discussed by E. Donath, J. R. Partington, O. Dieffenbach, A. M. Fairlie, E. J. Pranke, P. J. Fox, A. Frank and N. Caro, H. J. M. Creighton, W. G. Adam, C. S. Imison and W. Russell, P. Pascal and E. Decarrière, C. L. Parsons, A. T. Schlösing, V. I. Maliarewsky, and in many anonymous articles.

According to C. F. Schönbein, D. K. Tuttle, E. M. Peligot, and M. Berthelot and L. P. de St. Gilles, when copper is immersed in an aq. soln. of ammonia, it is oxidized, when exposed to air, and ammonia is simultaneously oxidized to nitrite; S. Kappel said that some nitrate is also formed. E. Müller found that with small proportions of dissolved copper in the catalytic oxidation of aq. ammonia to nitrite by oxygen in the presence of sodium hydroxide, the velocity of the reaction is proportional to the conc. of copper, to the press. of the oxygen, and to the conc. of the hydroxyl ions. The speed of nitrite formation increases with increasing conc. of ammonia, and with rise of temp. The presence of ammonium salts retards the change by removing hydroxyl ions. With solid copper, the activity is due to the presence of copper in soln., forming cuprous ions which are very active; and solid cuprous oxide is an active catalyst. The changes of potential of a copper anode in $2N$-NaOH, in the presence and absence of ammonia, are consistent with the hypothesis that tervalent copper ions play an intermediate rôle in the mechanism of the catalysis. Thus, bivalent copper ions may form tervalent ions by means of charges from hydrogen ions oxidized to water; the tervalent ions then react with hydroxyl ions in the presence of ammonia to give nitrite ions and reform bivalent copper ions. Similarly with cuprous ions. The hypothesis, thus expressed in the language of ions, means that the catalytic activity of copper is attributed to the capacity of copper to form higher oxidation products in soln.

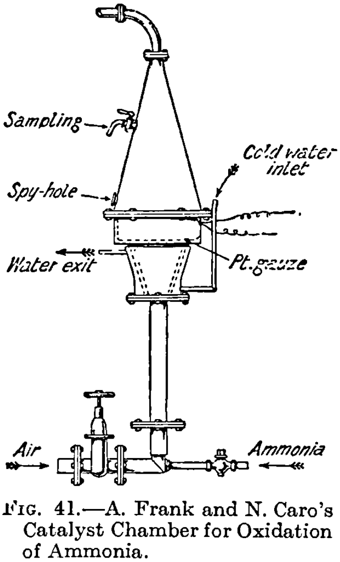

FIG. 41.—A. Frank and N. Caro's Catalyst Chamber for Oxidation of Ammonia.

W. Traube and A. Biltz found that in the electrolysis of an aq. soln. of sodium hydroxide containing ammonia, using platinum or iron electrodes, and a current of 5 to 10 ampères, virtually no nitrite is formed, but if some copper hydroxide be present, almost all the oxygen evolved at the anode is consumed in converting the ammonia into ammonium nitrite. As the electrolysis proceeds, the amount of nitrite formed gradually increases, and then, after a certain time, decreases owing to the oxidation to nitrate; if the electrolysis be continued for a considerable time, the liquid at the anode is found to contain only nitrate and no nitrite. A soluble alkaline earth may be substituted for the fixed alkali. When no free alkali is present, the formation of nitrite ceases, but if care is taken to keep the anode compartment permanently alkaline, the production of nitrite continues until a very concentrated soln. is obtained. In addition to the nitrite formation, a small amount of nitrate is also produced at the expense of the nitrite. The amount of this is small at the beginning, but tends to increase, even when an excess of alkali is present, as the ratio of the conc. of the nitrite to the conc. of ammonia increases. The conversion of nitrite into nitrate in the strongly alkaline liquid is accelerated by the presence of small amounts of cupric hydroxide. If the amount of alkali hydroxide in the anode compartment becomes less and less and finally completely disappears, so that at the end only an ammoniacal soln. is present, it is found that a rapid oxidation of nitrite to nitrate occurs, but even this is accelerated by the presence of the cupric hydroxide so long as free alkali is still present. In presence of much ammonia, the amount of nitrite can be increased to about 11 per cent. before oxidation to nitrate begins, whilst from an 11 per cent. nitrite soln. to which ammonia, sodium hydroxide, and copper hydroxide had been added a soln. containing as much as 17 per cent. nitrite was obtained on hydrolysis. E. Müller and F. Spitzer said that the electrolytic oxidation of ammonia to nitrite occurs in the presence of sodium hydroxide even in the absence of copper compounds. A. Brochet and G. Boiteau found that when an aq. soln. of ammonia is electrolyzed, using electrodes of graphite, a mixture of ammonium carbonate and nitrate is produced. The quantity of nitrate formed increases if ammonium carbonate or nitrate is first added to the soln. A similar reaction takes place if platinum or iron electrodes are used to electrolyze soln. of ammonium carbonate or nitrate in ammonia. The yield of nitrate was always low, it increases with current density, and the rate of formation decreases when the conc. of nitrate in soln. is high. G. Oesterheld electrolysed a sat. ammoniacal soln. of ammonium carbonate, and cooled the washed and dried gases. The mixture has a colour which may be exactly imitated by dipping a test-tube containing liquid air in liquid nitrogen trioxide, and, after a frozen layer has been formed, in liquid nitrogen tetroxide. The two layers of blue and yellow give a green which is exactly like that of the supposed hexoxide. The electro-oxidation of ammonia has been investigated by F. Balla, F. Grieshaber, etc.

According to T. P. Blunt, a mixture of ammonia and air may be kept in darkness without change, but in light there is a reaction attributed to the formation of ozone. L. I. de N. Ilosva found that **ozone** does not act on dry ammonia; but F. M. Baumert found that with ozonized oxygen and ordinary ammonia gas, clouds of ammonium nitrate are formed. L. Carius passed ozonized oxygen into an aq. soln. of ammonia, and found that some ammonium nitrite and nitrate are formed as well as a little hydrogen dioxide. The reaction was studied by F. Goppelsröder. W. Strecker and H. Thienemann observed that ozone is completely reduced when passed into liquid ammonia cooled by a mixture of carbon dioxide and ether. The products of the reaction contain about 98 per cent. of ammonium nitrate and 2 per cent. of nitrite: $2NH_3+4O_3=NH_4NO_3+4O_2+H_2O$; and $2NH_3+3O_3=NH_4NO_2+3O_2+H_2O$. When ozone is first passed into the liquid an orange colour is produced which may be due to the formation of an unstable ozonide. Carefully dried ozone at first acts very slowly on liquid ammonia. W. Weith and A. Weber reported that **hydrogen dioxide** and aq. ammonia react, forming nitrous acid or ammonium nitrite; on the contrary, F. Hoppe-Seyler could find no nitrite as a result of keeping a conc. soln. of hydrogen dioxide in contact with ammonia

—with or without the addition of sodium hydroxide—but if the soln. be evaporated in a retort at its b.p., the nitrite is formed. According to W. R. Hodgkinson and A. H. Coote, if an ammoniacal soln. of hydrogen dioxide be allowed to act for 5 mins. on pieces of metal approximately the same size, the losses in weight are: cadmium, 7 per cent.; copper, 1·4 to 3·6 per cent.; zinc, 3·9 per cent.; copper-nickel alloy, 0·1 per cent.; and in the presence of an ammoniacal soln. of hydrogen dioxide and ammonium nitrate, the losses were, cadmium, 18 per cent.; copper-nickel alloy, 1·0 per cent. A. W. Browne and O. R. Overman observed no indication of the formation of appreciable quantities of nitrous or nitric acid when ammonium sulphate in sulphuric acid soln. is treated with oxidizing agents such as hydrogen dioxide; potassium chlorate, persulphate, permanganate, or iodate; hydrated ferric oxide; or mercuric oxide or chloride. Ammonium sulphate soln. strongly acidified with sulphuric acid is but slightly affected at the b.p. by such oxidizing agents as hydrogen dioxide, or potassium chlorate or permanganate. F. Kuhlmann oxidized the whole of the nitrogen in ammonium sulphate to nitrite by treatment with potassium chlorate; and to nitrate by manganese dioxide, the higher lead oxides, or potassium permanganate and sulphuric acid. C. F. Schönbein, and F. Wöhler found that an aq. soln. of ammonia is oxidized by manganese dioxide when the mixture is shaken along with platinum sponge. S. Cloez and E. Guignet said that in the cold, ammonia is oxidized to nitrite by potassium permanganate, and to nitrate when heated with an excess of the permanganate; and L. P. de St. Gilles said that the oxidation proceeds rapidly if formic acid be also present. P. A. Bolley said that the ammonia is not oxidized by potassium permanganate if the soln. be very dil. O. T. Christensen observed the formation of nitrate during the decomposition of ammonium permanganate by heat.

According to H. Moissan,[3] **fluorine** reacts with ammonia with the production of a yellow flame, while with a soln. of ammonia each bubble of fluorine gives a flame accompanied by a detonation. The gas burns at ordinary temp. in **chlorine**, forming ammonium chloride and nitrogen: $8NH_3+3Cl_2=6NH_4Cl+N_2$. A. Valentini devised an apparatus for demonstrating this. F. Donny and J. Mareska found that strongly cooled liquid chlorine reacts vigorously with ammonia. According to P. L. Simon, when chlorine is passed in successive bubbles into conc. aq. ammonia, each bubble produces a slight explosion, and a flash of light, visible in the dark. If the ammonia be in excess, nitrogen is evolved, and ammonium chloride is formed; but if an excess of chlorine acts on ammonia, or on an ammonium salt, nitrogen chloride is produced—*vide infra*, nitrogen chloride. A. J. Balard, and E. J. Maumené said that by rapidly mixing chlorine water and aq. ammonia, hydroxylamine chloride is formed. A. J. Balard found that **bromine** reacts with ammonia, forming nitrogen and ammonium bromide. According to A. Bineau, ammonia gas reacts with **iodine** in the cold, forming a viscid liquid which, when treated with water, decomposes into ammonium iodide, nitrogen iodide, and hydrogen. In the presence of alcohol, iodine decomposes ammonia, forming ammonium iodide, diiodoamide, and nitrogen iodide. W. H. Seamon obtained what he regarded as *amminodiiodide*, NH_3I_2, by the action of dry ammonia on dry iodine, and allowing the product to stand for some time over conc. sulphuric acid. F. Raschig said that the product of the reaction between dry iodine and ammonia depends on the temp. C. Hugot, and O. Ruff obtained a number of different substances by the action of iodine on liquid ammonia—*vide infra*, nitrogen iodides. C. F. Schönbein found that the product of the action of aq. ammonia and iodine water has bleaching qualities and probably contains ammonium hypoiodite; some ammonium iodide and iodate are also formed. For the action of the **hydrogen halides**, and of the **halide acids**, *vide* the corresponding ammonium salts. L. Troost, working with dried ammonia and hydrogen chloride, obtained *ammonium hexamminochloride*, $NH_4Cl.6NH_3$, melting at −18°; and *ammonium triamminochloride*, $NH_4Cl.3NH_3$, melting at 7°. The dissociation press. of the triammine is 140 mm. at −36°; 485 mm. at −13°; 730 mm. at −60°; 1035 mm. at 0°; and 1800 mm. at 8°. The hexammine has a dissociation press. of 580 mm. at —36° ; 750 mm. at —31·5° ; and 1130 mm. at —21°. A. J. Balard found that gaseous ammonia detonates in contact with **hypochlorous acid,** and chlorine is liberated, while a conc. aq. soln. is decomposed by ammonia gas with the liberation of free nitrogen and chlorine, and the evolution of heat and light ; in the cold, hypochlorous acid reacts with aq. ammonia, forming nitrogen chloride. Soln. of **sodium hypochlorite** decompose ammonia and ammonium salts evolving all the nitrogen as a gas. J. Thiele said that hydrazine and hydroxylamine are formed as intermediate products. T. Oryng found the reaction is of the second order ; and with the proportions $3NaOCl+2NH_3=3NaCl+N_2+3H_2O$, at 15°–25°, the oxidation of the ammonia to nitrogen is never complete. The effect of inert solvents is not alone determined by the viscosity. The reaction is accelerated by copper, mercury, lead, iron (ic), cobalt, nickel, titanium, platinum, manganese, and chromium salts. The reaction was also studied by A. Bineau, C. F. Schönbein, J. Kolb, H. J. H. Fenton, A. J. Balard, G. Lunge and R. Schoch, C. F. Cross and E. J. Bevan, J. Effront, and F. Raschig. Other products reported are nitrogen chloride (A. J. Balard, F. Raschig, and G. Lunge and R. Schoch), chloramide (F. Raschig), and chlorates (C. F. Schönbein). Soln. of **sodium hypobromite** or barium hypobromite, or a soln. of bromine water in alkali-lye decompose ammonia and ammonium salts as in the analogous case with hypochlorites. D. R. Nanji and W. S. Shaw observed that traces of nitrites and nitrates are formed during the reaction. F. von Stadion found that ammonia with **chlorine dioxide** furnishes at ordinary temp. nitrogen and ammonium chloride and chlorate. A. Ditte observed no action between ammonia and **iodine pentoxide** at ordinary temp., but when warmed, a vigorous reaction occurs with the formation of iodine, nitrogen, and water. G. Denigès found that when a drop of a 10 per cent. aq. soln. of iodic acid is exposed to an atm. containing ammonia, it immediately becomes covered with a crystalline film of the normal iodate, NH_4IO_3. None of the volatile amines examined give this reaction under these conditions. G. Denigès and J. Barlot added that if a drop of a 50 per cent. soln. of iodic acid is exposed to an atm. containing a trace of ammonia gas, it becomes covered with a thin white film, and if this is then well mixed with the iodic acid, rhombic crystals of ammonium tri-iodate can be observed under the microscope. If a drop of 50 per cent. iodic acid and a drop of conc. aq. ammonia are placed a few mm. apart on a microscope slide, the successive formation of the neutral iodate, the di-iodate, and the tri-iodate may be observed. K. A. Hofmann and W. Linnmann found that gaseous ammonia, mixed with air, reacts so vigorously with solid **potassium chlorate** that the reaction may become dangerous if the conc. of the ammonia is high. It is therefore advisable to dilute the chlorate by admixture with clay. The reaction begins at about 250°, and the heating is discontinued until the violence of the reaction has subsided. The course of the reaction is symbolized: $KClO_3+2NH_3 \rightarrow KCl+N_2+3H_2O$, and $KClO_3+N \rightarrow KNO_3+Cl$. The ammonia reacts directly with the chlorate and not with previously liberated oxygen, the change occurs at the surface of the chlorate and not in the gaseous layer, and the nitric acid is not formed intermediately. The incidence of the reaction is ascribed to the relatively unsaturated nature of the potassium chlorate and ammonia molecules and the consequent possibility of the production of intermediate additive products. In confirmation of this view, it is shown that the sat. potassium perchlorate mol. does not react with ammonia at moderate temp., and that, at higher temp., the production of nitrate is due entirely to the intermediate formation of potassium chlorate.

According to A. F. de Fourcroy,[4] if the vapour of **sulphur** and ammonia be led through a red-hot tube, hydrogen, nitrogen, and a crystalline mixture of ammonium mono- and poly-sulphides are formed. F. Jones said that dry sulphur absorbs ammonia, and when the product is heated, ammonium sulphide is formed. A. Smith and W. B. Holmes found that if ammonia gas be passed over molten sulphur no insoluble sulphur is formed during the cooling. C. A. Seely found that liquid ammonia dissolves sulphur, forming, according to H. Moissan, and C. Hugot, a soln. of *sulphoammonium.* E. C. Franklin and C. A. Kraus noted the dissolution of sulphur in liquid ammonia occurs only in the presence of air—*vide infra.* O. Ruff and E. Geisel found the reaction between sulphur and liquid ammonia is reversible: $10S+4NH_3 \rightleftharpoons 6H_2S+N_4S_4$. C. Brunner showed that aq. ammonia dissolves no sulphur at a temp. below 75°, or, according to F. A. Flückiger, below 60°–65°; but at 90° or in a boiling soln., the liquid acquires a pale lemon-yellow colour, while ammonium thiosulphate and sulphide are formed. J. B. Senderens said that a reaction occurs even at 12°; and F. A. Flückiger added that under press. in a sealed tube at 90°–100°, ammonia-water of sp. gr. 0·885 forms a deep yellowish-brown soln. of ammonium polysulphide, which, when the tube is opened, deposits crystals of sulphur. L. Troost obtained three *ammonium amminosulphides* by the action of ammonia on **hydrogen sulphide.** M. J. Fordos and A. Gélis showed that cold ammonia gas in contact with **sulphur dichloride,** SCl_2, produces brownish-red, or, with more ammonia, pale lemon-yellow flecks containing respectively the diammine, $SCl_2.2NH_3$, and the tetrammine, $SCl_2.4NH_3$; sulphur dichloride dropped slowly into an aq. soln. of ammonia was found by M. J. Fordos and E. Gélis to produce ammonium thiosulphate, sulphate, chloride, and sulphur amminonitride, and dichloride. E. Soubeiran, and K. Martens said that dry ammonia and **sulphur chloride,** S_2Cl_2, form a tetrammine, $S_2Cl_2.4NH_3$. A. K. Macbeth and H. Graham represented the reaction: $6S_2Cl_2+16NH_3=N_4S_4+12NH_4Cl+4S_2$, and added that other nitrogen sulphides—*e.g.* N_2S_5 and S_6NH_2—may be formed—*vide* the sulphur chlorides. The action of ammonia on **thionyl chloride** gives a white cloud of ammonium chloride, a yellow mass of nitrogen sulphide, and what A. Michaelis thought might be nitrogen chlorosulphide; H. Schiff said that thionyl amide is not formed. The reaction was discovered by H. Piotrowsky. H. V. Regnault said that **sulphuryl chloride** mixed with ethylene chloride reacts with dry ammonia, forming a mixture of sulphuryl amide, $(NH_2)SO_2$, and ammonium chloride. The reaction was further studied by A. Mente, F. Michel, A. Hantzsch and co-workers, and M. Traube, and it was shown that sulphimide, sulphomelide, sulphamide, nitrogen trisulphide, etc., were formed. H. Rose observed that when ammonia is passed slowly into cold **pyrosulphuryl chloride,** a white mass of the tetrammine, mixed with ammonium chlorosulphide, and sulphate is formed. According to J. W. Döbereiner, **sulphur dioxide** reacts with ammonia, forming a brownish-yellow vapour which condenses to a brown solid mass of anhydrous ammonium sulphite, which, with a small proportion of water, furnishes ordinary ammonium sulphite. H. Rose concluded that with the dry gases, an orange-red viscid or crystalline mass is produced which is very deliquescent, and dissolves easily in water, without evolving ammonia. The soln. is neutral, and when freshly prepared contains ammonium sulphite, sulphate, trithionate, etc. H. Rose supposed the orange-red substance to be a compound of ammonia with an isomeride of sulphur dioxide; G. Forchhammer, a mixture of ammonium sulphate, and sulphur diamide, $S(NH_2)_2$; H. Watts, a mixture of amidosulphinic acid, $NH_2.SO.OH$, and its ammonium salt; S. M. Jörgensen, ammonium pyroamidosulphinate, $NH_2.S_2O_4.NH_4$. E. Divers and M. Ogawa found that if the mixed gases are thoroughly dried, and at a low temp., no reaction occurs; but at a higher temp., with the sulphur dioxide in excess, a substance, ammonium amidosulphinate, $NH_2.SO.ONH_4$, or SO_2NH_3, is formed, and if the ammonia is in excess, amidosulphinic acid, $NH_2SO.OH$, or $SO_2(NH_3)_2$, is produced. The reaction was studied by H. Piotrowsky, and H. Schumann—*vide* amidosulphinites. When an ethereal soln. of ammonia is treated with sulphur dioxide, ammonium amidosulphinate is formed. For the action of **sulphur trioxide,** *vide infra.*

According to A. Loir and C. Drion, when liquid ammonia at −65° is poured on to conc. **sulphuric acid,** the liquids do not mix, and a reaction gradually sets in. According to V. A. Jaquelain anhydrous ammonia reacts with sulphuric acid, forming sulphamide, and, according to A. Woronin, ammonium amidosulphate, For sulphurous and sulphuric acids, *vide* the corresponding ammonium salts. R. Kempf represented the reaction with the **persulphate** resulting in the formation of nitrogen and a trace of nitric acid: $4Na_2S_2O_8+NH_3+9NaOH=NaNO_3+8Na_2SO_4+6H_2O$; and $3(NH_4)_2S_2O_8+8NH_3=6(NH_4)_2SO_4+N_2$. H. Marshall made some observations on this reaction. G. Scagliarini and G. Torelli said that in the oxidation of ammonia by either potassium or ammonium persulphate, the oxygen of the latter first oxidizes the ammonia to nitrous acid, which is converted by the excess of ammonia into ammonium nitrite, this being decomposed with liberation of nitrogen by the heat developed. Copper appears to act as an oxygen-carrier. D. M. Yost said that the rate of oxidation of aq. ammonia by the persulphate ion is directly proportional to the conc. of the oxidizing agent, and to the conc. of the catalyst—the $Ag(NH_3)_2$-ion. The rate of oxidation increases less rapidly than the rate of increase of the conc. of the ammonia. F. A. Flückiger said that **selenium** does not act on ammonia gas, or on aq. ammonia. E. C. Franklin and C. A. Kraus noted the dissolution of selenium in liquid ammonia occurs only in the presence of air. R. Epenschied showed that **selenium tetrachloride** reacts at ordinary temp. with dried ammonia mixed with air, forming selenium, ammonium chloride, nitrogen, and hydrogen; if the mixture be well-cooled, a brown mass of nitrogen selenide and ammonium chloride is formed. A. Michaelis obtained selenium, nitrogen, ammonium chloride, and selenium dioxide by the action of **selenyl chloride,** $SeOCl_2$; V. Lenher and E. Wolensensky found that with a benzene or toluene soln. of selenyl chloride, $SeOCl_2$, ammonia forms nitrogen selenide or a mixture of this and selenium. A. Michaelis represented the reaction with **selenium dioxide** by: $4NH_3+3SeO_2=6H_2O+3Se+2N_2$. R. Metzner gave for the reaction between **tellurium tetrachloride** and dry ammonia at 200°–250°: $3TeCl_4+16NH_3=3Te+12NH_4Cl+2N_2$; at 0°, tellurium triamminotetrachloride, $TeCl_4.3NH_3$, is formed.

A. T. Larson and C. A. Black[5] measured the solubility of **nitrogen** (*q.v.*) in liquid ammonia. E. J. B. Willey and E. K. Rideal found that ammonia is decomposed by activated nitrogen. W. Henry found that a mixture of **nitrous oxide,** with not less than one-seventh or more than three-fourths ammonia, explodes when sparked, forming water, nitrogen, and oxygen, and with an excess of nitrous oxide, nitrogen dioxide may be formed. G. Bischof said that some of the ammonia is decomposed into hydrogen and nitrogen. W. Wislicenus noted the action of sodamide on nitrous oxide, forming hydrazoates. W. Henry found that **nitric oxide** behaves towards ammonia in an analogous way to nitrous oxide when sparked. J. L. Gay Lussac found that a mixture of equal vols. of ammonia and nitric oxide gases condenses in the course of a month to about half its original vol., without undergoing complete decomposition—nitrogen and probably nitrous oxide are formed. Aq. ammonia in contact with nitric oxide produces nitrous oxide. The Badische Anilin- und Soda-fabrik found that interaction between nitric oxide and ammonia gas does not occur under ordinary conditions. P. L. Dulong found that both liquid and gaseous **nitrogen peroxide** rapidly decompose ammonia at ordinary temp., forming nitric oxide and nitrogen; and E. Soubeiran found that if the ammonia and nitrogen peroxide be dried and freed from air, the vigorous reaction furnishes nitrogen, water, and ammonium nitrite; but if traces of water and air be present, some nitrous oxide and ammonium nitrate are also formed. A. Besson and G. Rosset found that at —80° liquid ammonia reacts with solid nitrogen peroxide with explosive violence. According to P. T. Austen, a fine stream of ammonia gas in an atm. of **nitric acid** vapour burns with a yellow flame.

According to A. Bineau, **phosphorus** sublimes in ammonia gas without absorption taking place, but C. W. Böckmann, and A. Vogel said that a phosphorus amminoxide can be so prepared. F. A. Flückiger found that dry phosphorus slowly absorbs ammonia, forming a dark brittle substance; and when phosphorus is warmed with aqua ammonia, a black compound of phosphorus oxide and ammonia is produced. A. F. de Fourcroy found that when the vapour of phosphorus and ammonia are sent through a red-hot tube, phosphine and nitrogen are formed. E. C. Franklin and C. A. Kraus found liquid ammonia dissolves phosphorus only in the presence of air. H. Rose, and J. Persoz found that **phosphorus trichloride** rapidly absorbs ammonia, forming a white cloud. Much heat is developed and phosphorus amminotrichloride is formed, and this, when heated, decomposes : $5PCl_3+8NH_3=4PN_2H+15HCl+5H+P$—*vide* phosphorus trichloride. H. Rose found **phosphorus tribromide** acts in an analogous manner. C. Hugot represented the reaction with strongly cooled, liquid ammonia : $15NH_3+PBr_3=P(NH_2)_3+3NH_4(NH_3)_3Br$. Cold **phosphorus pentachloride** absorbs ammonia very slowly if at all, but if not so strongly cooled, an amminopentachloride is formed. J. von Liebig and F. Wöhler always found ammonium chloride was present, showing that some decomposition had taken place. C. Gerhardt represented the reaction by $4NH_3+PCl_5=(NH_2)_2PCl_3+2NH_4Cl$—*vide* phosphorus pentachloride. J. H. Gladstone observed the reaction occurs when the gases are moist or dry. H. Schiff represented the reaction with **phosphoryl chloride :** $POCl_3+6NH_3=(NH_2)_3PO+3NH_4Cl$. J. H. Gladstone found that at 0° the reaction is better represented by $POCl_3+2NH_3=NH_4Cl+NH_2.POCl_2$; and at 100°, $POCl_3+4NH_3=2NH_4Cl+(NH_2)_2POCl$—*vide* phosphoryl chloride. According to A. Bineau, **phosphorus trisulphide** absorbs ammonia very slowly, after 6 months' action the product had the composition $(NH_3)_2P_2S_3$. A. Baudrimont, G. Chevrier, and J. H. Gladstone and J. D. Holmes observed that **thiophosphoryl chloride** absorbs dry ammonia, forming ammines ; and H. Schiff, and G. Chevrier noted the formation of some phosphorus sulphotriamide. J. H. Gladstone and J. D. Holmes found that a dil. aq. soln. of ammonia reacts with thiophosphoryl chloride, forming thiophosphaminic acid ; and with an excess of ammonia, G. Chevrier obtained ammonium thiophosphate. A. Michaelis found that **thiophosphoryl bromide** is decomposed with difficulty by ammonia in the cold, but when heated various substances are formed—sulphur, ammonium polysulphide, ammonium phosphite, and phosphate. H. Schiff said that ammonia and **phosphorus pentoxide** furnish pyrophosphodiaminic acid, and S. Gutmann, and H. Biltz obtained a suboxide (*q.v.*). H. B. Baker showed that if the ammonia and phosphoric oxide are quite dry, no reaction occurs. T. E. Thorpe and A. E. Tutton showed that ammonia acts on a soln. of **phosphorus trioxide** in alcohol or benzene, forming a diamide and an ammonium salt of phosphorous acid. A. Stock studied the action of liquid ammonia on **phosphorus pentasulphide** (*q.v.*). Ammonia forms ammines when it reacts with the **arsenic trihalides.** A. Rosenheim and F. Jacobsohn found that **arsenic pentoxide** reacts with liquid ammonia, forming the ammine, $As_2O_5.3NH_3$; but **antimony pentoxide** does not react.

L. Clouet,[6] C. Langlois, F. Kuhlmann, and C. Weltzien found that when ammonia is passed over red-hot **carbon,** ammonium cyanide and hydrogen are formed: $2NH_3+C=NH_4CN+H_2$; some nitrogen is also formed, but, according to C. Weltzien, no hydrocarbons are produced. The production of cyanides by the action of ammonia on carbon has been investigated by E. Bergmann, and G. A. Voerkelius. H. Delbrück showed that hydrogen cyanide is produced when ammonia and carbon dioxide are passed over heated potassium. R. M. Badger gave for the equilibrium constant, $[H_2][HCN]=K[NH_3]$, in the balanced reaction : $NH_3+C=HCN+H_2$, at 800°, $K=5{\cdot}8\times10^{-6}$. A. Millot showed that when a soln. of ammonia is electrolyzed with a positive electrode of purified gas-carbon and a negative electrode of platinum, the liquid acquires a deep black colour. If this black soln. is evaporated to dryness on a water-bath, and the residue extracted with warm alcohol, a black insoluble substance is left, and a yellow soln. is obtained. When this soln. is evaporated to a syrup, it deposits a yellowish nitrogenous substance, soluble in boiling water, to which it imparts an acid reaction. The still liquid portion is evaporated repeatedly until no further deposit is obtained, and when the filtered liquid is allowed to cool it deposits crystals of carbamide. In this reaction, the synthesis of carbamide is effected by the direct action of carbonic anhydride and ammonia under the influence of the electric current. The electrolysis, during eight days, of 500 c.c. of ammonia mixed with an equal volume of water gave 6–8 grms. of the black substance and one grm. of pure carbamide. The subject has been investigated by L. Weisberg, H. von Wartenberg, and W. Bertelsmann. The formation of cyanides by the action of ammonia on the vapours of **hydrocarbons** was studied by F. Kuhlmann, D. Lance and R. L. E. de Bourgade, H. C. Woltereck, J. Mactear, P. R. de Lambilly, and C. Beindl. J. W. Beeson and J. R. Partington exploded mixtures of varying quantities of ammonia with 2 vols. of **carbon monoxide** and one vol. of oxygen at 85° and 380 mm. press. so that no steam was condensed. All the mixtures which could be ignited approximated a 95·3 per cent. decomposition of the ammonia. With some mixtures containing more than 40·5 per cent. of ammonia, the first spark did not cause explosion, a period of induction being observed, after which the propagation of the flame from the spark to the walls of the bulb was so slow that it could be followed visually. No ignition occurred in mixtures in which the ratio $NH_3/(2CO+O_2)$ exceeded 0·924. F. Kuhlmann found that under the influence of platinum black, carbon monoxide and ammonia react: $NH_3+CO=H_2O+HCN$; A. Mailhe and F. de Godon obtained an excellent yield of ammonium cyanide by using thoria as a catalyst at 410° to 450°—if alumina or zirconia is used as catalyst, a higher temp. is necessary. H. Jackson and D. N. Laurie obtained both urea and ammonium cyanate when the gases react in contact with a hot surface of platinum: $CO+NH_3=H_2+HOCN$. K. C. Bailey found that under the influence of radium emanation the second reaction occurs—the first reaction occurs only in the presence of a catalyst. The reaction was studied by G. Bredig and E. Elöd, M. Herbst, and R. K. Müller. The action of **carbon dioxide** on ammonia has been discussed in connection with the carbamates (**2**. 20, 34); the action of **carbonyl chloride** on ammonia and ammonium chloride (**5**. 39, 28); the action of carbon disulphide (**6**. 39, 42); and the action of **carbonyl sulphide** (**6**. 39, 29). K. C. Bailey observed that under the influence of radium emanation carbon dioxide and ammonia react, forming cyanate and urea. The solubility of ammonia in various carbon compounds has been discussed in the preceding section. A. B. Brown and E. E. Reid studied the alkylation of ammonia by passing mixtures of ammonia and alcohol—methyl, ethyl, η-propyl, and η-butyl—over various oxides as catalysts at 300°–500°. They found, in the order of ascending efficiency, blue oxide of tungsten, commercial silica gel, alumina, silica gel impregnated with nickel oxide, zirconia, silica gel impregnated with thoria, and a silica gel prepared by adding a sodium silicate soln. (4·5 per cent. Na_2O) to an equal volume of 10 per cent. pure hydrochloric acid. The resulting gel is broken into large fragments, suspended in running water for several days, and then dried at temp. rising in stages to 180°. For high activity, long life, and absence of side reactions, the special silica gel is much the best. The optimum temp., percentages of alcohol converted into amines, and the ratios of primary, secondary, and tertiary amines formed, using this catalyst, are as follow: methyl, 480°, 56 per cent., 5 : 12 : 3; ethyl, 465°, 39·5 per cent., 2 : 5 : 3; η-propyl, 415°, 49 per cent., 10 : 11 : 18; η-butyl, 430°, 25 per cent., 11 : 11 : 3. G. W. Dorrell studied the catalytic activity of alumina whose optimum temp. is about 300°. L. Knorr studied the action of ammonia on **ethylene oxide**; M. Knothe, on **acid dichlorides**; F. Dobler, on aromatic **aldehydes**; F. Bidet, on primary **amines**, etc. G. Baume, and A. M. Wasilieff studied the system with **methyl ether** and **ethyl alcohol** with ammonia; and C. A. Kraus and E. H. Zeitfuchs, equilibrium in liquid mixtures of ammonia and xylene. H. H. Schlubach and H. Miedel observed that ammonia or ammonium salts may act as a reducing agent on some organic compounds—phenylbutylene, styryl methyl ketone, pyridine, and nitrobenzene, but not acetophenone, benzil, benzoin, and deoxybenzoin. A soln. of sodium in liquid ammonia is added gradually to a soln. of ammonium chloride in the same solvent in which the substance to be reduced is at least partly dissolved at —80° to —50°. If the compound under investigation is not sufficiently soluble in liquid ammonia, benzene or ether may be added. In general, reduction appears to be due to the direct addition of nascent hydrogen without preliminary formation of an intermediate additive compound with the sodium. The action is highly selective and appears to resemble most closely that of sodium and alcohol. Probably owing to the low temp. of the reactions, the formation of by-products is largely avoided. The reaction was studied by A. R. Ling and D. R. Nanji, L. C. Maillard, etc., when ammonia is brought in contact with dextrose (fused or in aq. soln.), either in the form of gas or aq. soln., at a moderate temp.—say 35°–40°—combination of the ammonia with the sugar takes place. If now the liquid be heated to a higher temp., *e.g.* 100°, a vigorous exothermic reaction ensues, and dark-coloured substances are produced. Similar reactions occur when certain amino-compounds are substituted for ammonia. A. Couder found that dry ammonia acts on **cyanamide,** forming colourless soln. containing dicyanodiamide. A. B. Brown and E. E. Reid discussed the alkylation of ammonia; and H. B. Merrill, the depilatory action on calf-skins.

The acid properties of soln. of ammonium salts in liquid ammonia have been established by E. C. Franklin and co-workers.[7] According to F. W. Bergstrom, these solns. react with most of the elements above hydrogen in the electrochemical series as it is known in water. The action of the **alkali metals** and of the **alkaline earth metals** on liquid ammonia is discussed in a special section, and the effect of the gas on the heated metals is indicated in connection with the amides, or nitrides. M. Copisarow, and R. Fricke and O. Suwelaek obtained rhythmic rings of a metal hydroxide by allowing ammonia gas to diffuse into a soln. of the metal salt in gelatin. Several metals form nitrides when heated in the gas—*e.g.* **magnesium, zinc, aluminium, iron, titanium,** etc.—in other cases—*e.g.* **silver, gold, platinum,** etc.—the metal exerts a catalytic action on the decomposition of ammonia—*vide supra,* nitrides. C. van Brunt said that the circumstances of an accidental explosion indicate that during 10 years at ordinary temp. **mercury** in the safety valve of a carboy containing conc. aq. ammonia, formed a *mercury ammonium oxide.* A. F. de Fourcroy showed that many **metal oxides** are decomposed when heated in ammonia gas, forming water, nitrogen, and the metal or a lower oxide. In the case of **mercuric oxide,** nitric acid is formed. Part of the nitrogen may be oxidized to nitric oxide or nitrogen peroxide. In some cases, nitrides of the metals are formed—*e.g.* **titanium, iron, or copper oxides**—and in other cases, complex compounds containing nitrogen, hydrogen, and oxygen may be formed—*e.g.* **tungstic or mercuric oxide** (*q.v.*). R. Tupputi, and E. Fleischer found aq. ammonia decomposes **nickel sesquioxide** in the cold, forming nitrogen and nickel monoxide. A. Rosenheim and F. Jacobsohn found that with liquid ammonia **molybdic oxide** furnishes the ammine $MoO_3.3NH_3$; and **tungstic oxide** is not changed, but **tungsten dichlorodioxide** forms the ammine $WoO_3.3NH_3$. G. W. Dorrell found that ammonia is readily absorbed by alumina at 344°, but no decomposition into its elements was noticed. H. Hiendlmaier studied the effect of ammonia on various **metal hydroxides** —copper, chromium, iron, and nickel—in the presence of weak acids. According to O. Michel and E. Grandmongin, heated **sodium dioxide** reacts with dry ammonia: $2NH_3+3Na_2O_2=6NaOH+N_2$—some sodium nitrite and nitrate are also formed; **barium dioxide** acts in an analogous manner; **manganese dioxide** forms manganese sesquioxide, nitrogen and water; and **lead dioxide** forms nitrogen, and ammonium nitrite and nitrate. F. W. Bergstrom found that **molybdenum and tungsten dibromides** and **tungsten dichloride** yield slightly soluble ammoniobasic halides on treatment with liquid ammonia. **Molybdenum tribromide and pentachloride,** and **tungsten pentabromide and hexachloride,** dissolve in liquid ammonia to give red soln., the first named also giving a precipitate of ammoniobasic bromides. Dilution of the soln. yields amorphous precipitates of indefinite composition. Molybdenum pentachloride absorbs 8 mols. of ammonia gas, giving a derivative of unknown composition.

Aq. ammonia dissolves many of the heavy **metal hydroxides**—*e.g.* zinc, cadmium, cobalt, nickel, copper, and silver hydroxides; chromic hydroxide dissolves in this menstruum but sparingly; and ferrous and manganese hydroxides dissolve only in the presence of ammonium salts. The solubility is supposed to be determined by the formation of a compound of ammonia with the respective oxides. Compounds formed by the direct addition of ammonia with the oxides and salts are usually called **ammines.** The oxides of vanadium, uranium, antimony, mercury, silver, gold, and the platinum metals form solid compounds which are more or less explosive. O. Ruff and E. Geisel found that the **alkali metal hydrides** react with liquid ammonia, forming amides: $MH+NH_3=H_2+M.NH_2$. The hydrides of potassium, rubidium, and cæsium react at the m.p. of liquid ammonia —78°; sodium hydride at about —40°; and lithium hydride requires many days at ordinary temp. before it is completely transformed into amide. Many **metal salts** unite with ammonia, sometimes with the evolution of heat. For example, ammonia is absorbed by calcium chloride, zinc chloride, silver chloride, etc., forming amminochlorides. A great many complex silver ammines with the monobasic salts have been reported in which the ratio $Ag:NH_3$ is as 1 : 2, for instance, $AgI.2NH_3$; $AgClO_3.2NH_3$; $AgBrO_3.2NH_3$; $AgNO_3.2NH_3$; $AgNO_2.2NH_3$; etc. With salts of higher basicity the proportion of ammonia is greater, *e.g.* $Ag_2CrO_4.4NH_3$; $Ag_2SeO_4.4NH_3$; $Ag_2SO_4.4NH_3$; $Ag_2S_2O_7.4NH_3$; $Ag_4As_2O_4.8NH_3$; etc., are known. Some of these compounds lose ammonia on exposure to air—*e.g.* manganese amminosulphate; and lead amminoiodide—others lose ammonia when heated—*e.g.* zinc amminosulphate; calcium amminochloride; and silver amminochloride—others give off ammonium salts mixed with more or less ammonia when heated—*e.g.* nickel amminochloride; and copper amminosulphate—and some reduced metal remains behind. Some of the ammines can be volatilized unchanged—*e.g.* zinc amminochloride; and ferric amminochloride. Aq. soln. of some of these compounds are quite stable—*e.g.* cobalt and platinum ammines—and even resist the action of acids and bases; others are decomposed by water into metal salt and ammonia—*e.g.* calcium amminochloride—and others again are hydrolyzed into a sparingly soluble basic salt, hydroxide, or oxide—*e.g.* zinc amminocarbonate; thallium amminochloride; lead amminoiodide; and ferric amminochloride. K. Alberts examined the effect of heating **potassium, calcium, strontium, barium, and magnesium sulphates** in a current of ammonia. A. von Unruh studied the action of dry ammonia on **uranyl salts.**

H. P. Cady and R. Taft sought if electrolytic oxidations can occur in systems containing no oxygen, and found that with liquid ammonia as solvent, thallous iodide, cuprous iodide, hydrazobenzene, and methyl- and ethylamine hydrochlorides can be oxidized. The properties of soln. of salts, etc., in liquid ammonia were studied by F. W. Bergstrom, T. J. Webb, E. C. Franklin and C. A. Kraus, etc.

H. Tamm[8] said that aq. ammonia is oxidized by **potassium permanganate,** forming ammonium nitrate; but S. Hoogerwerff and W. A. van Dorp found that an alkaline soln. of the salt is not affected by ammonia. F. Jones represented the reaction in neutral soln. by the equation $8KMnO_4+8NH_3=4Mn_2O_3+KNO_3+KNO_2+6KOH+9H_2O+3N_2$ in agreement with the effect of phosphine, arsine, and stibine on that liquid. The reactions with permanganates in the presence of other oxides have been studied by C. F. Schönbein, J. A. Wanklyn and A. Gamgee, and S. Cloez and E. Guignet. I. M. Kolthoff said that the oxidation of ammonia by permanganate is more dependent on concentration in acidic than in alkaline soln.

According to E. J. Maumené, **ammonium oxide,** $(NH_4)_2O$, which he called **chydrazaine,** is evolved when a soln. of potassium permanganate (11 grms.) and sulphuric acid (40 grms. SO_3) is added to dried crystalline ammonium oxalate (141·2 grms.); the whole well mixed, and gently heated until it begins to boil. The gas is absorbed in hydrochloric acid, a neutral soln. of *chydrazaïne chloride,* $(NH_4)_2O.2HCl$, is formed. The crystals of the salt are readily soluble in water, but only sparingly soluble in alcohol. The sublimed salt has no water of crystallization; when an excess of a soln. of the chloride is mixed with one of platinum tetrachloride, yellow crystals of *chydrazaïne chloroplatinate,* $(NH_4)_2O.H_2PtCl_6$, are formed, but if the platinum tetrachloride be in excess, the crystals contain more chloroplatinate. The crystals of *chydrazaïne sulphate* are soluble in water and sparingly so in alcohol. *Chydrazaïne nitrate* is crystalline and an aq. soln., on evaporation, furnishes nitric acid, nitrogen, nitrogen peroxide, and *imide*, N_3H_2. None of these claims has been established.

Some reactions of analytical interest.—Ammonia is recognizable by its smell; the aq. soln. gives a blue coloration with litmus, lacmoid, and resazurin; a red colour with rosalic acid; and a brown colour with turmeric. White fumes appear when ammonia vapour is near the vapour of a volatile acid—hydrochloric or acetic acid. Ammonium salts give off ammonia when heated in contact with lime, or alkali hydroxides. An alkaline soln. of potassium iodomercurate, the so-called **Nessler's reagent,**[9] gives a brown precipitate with ammonia, and the colouring power is so great that minute traces of ammonia can be detected by its means. The reaction is also adapted to a colorimetric process for the quantitative determination of ammonia in water, etc. S. S. Graves proposed to substitute Nessler's reagent by one prepared by adding 130 c.c. of water and 100 c.c. of cold, sat. soln. of mercuric chloride to 80 grms. of sodium chloride. The mixture is shaken until the sodium chloride has dissolved, and 70 c.c. of a sat. soln. of lithium carbonate (1 per cent.) is added slowly, with shaking, so that mercuric oxide is not deposited on the sides of the flask. The soln. is usually cloudy, owing to the presence of ammonia in the substances used, but if well shaken with 3 to 5 grms. of talc powder and filtered, a clear liquid can be obtained. The soln. can be kept almost indefinitely in carefully stoppered bottles. Ammonium salts give a yellow crystalline precipitate with **hydrochloroplatinic acid,** and, unlike the corresponding precipitate with potassium salts, the precipitate on ignition leaves only platinum behind; and when the precipitate is treated with alkali-lye, ammonia is given off. According to J. L. Lassaigne, one part of ammonium chloride in 100 parts of water gives a copious precipitate; with 200 parts of water, a slight precipitate; with 400 parts of water, a very slight precipitate; and with 800 parts of water, a scanty precipitate after 12 hrs. A white precipitate of ammonium hydrotartrate, $COOH.HCOH.HCOH.COONH_4$, is produced with **tartaric acid**—the presence of sodium acetate favours the precipitation. The precipitate is soluble in alkali-lye, and mineral acids. **Sodium hydrotartrate** also gives a white precipitate with conc. soln. Potassium salts behave in an analogous manner. Unlike potassium salts, ammonium salt soln. give no precipitate with **perchloric acid**; and unlike sodium salts, no precipitate with **potassium pyroantimonate.** Both ammonium and potassium salts give precipitates with **picric acid, sodium tungstate, phosphomolybdic acid,** and **sodium nitratocobaltate.**

The ammonium salts are decomposed, with the evolution of nitrogen, when they are treated with **hypobromites,** or **hypochlorites**: $2NH_3+3NaOBr=N_2+3NaBr+3H_2O$. According to A. Trillat and M. Turchet,[10] when soln. of potassium iodide and an alkali hypochlorite are added to a liquid containing ammonia, an intense black coloration is produced due to the formation of nitrogen iodide, and as the same result is obtained when the iodine mono- or tri-chloride and an alkali are used instead of the above reagents, the reaction may be represented by the following equation: $3ClI+NH_3+3NaOH=3NaCl+NI_3+3H_2O$. In applying the test, 3 drops of a 10 per cent. soln. of potassium iodide and 2 drops of a conc. soln. of alkali hypochlorite (Eau de Javel) are added to 20 or 30 c.c. of the suspected water; the use of excess of the reagents must be avoided, as nitrogen iodide dissolves under these conditions. No compounds of nitrogen other than ammonium salts are said to form nitrogen iodide under these conditions. According to E. Riegler, if ten c.c. of the soln. to be tested is mixed with 10–15 drops of a soln. of **p-nitroaniline,** hydrochloric acid, and sodium nitrite, and a 10 per cent. soln. of sodium hydroxide be added drop by drop, the liquid becomes yellow or red if ammonia be present. According to H. Rose,[11] and J. Müller, water containing traces of ammonia colours a soln. of **mercurous nitrate** a dirty grey colour; and mercurous nitrate test-papers are coloured black by ammonia vapours. According to E. Bohlig, when a soln. of **mercuric chloride** is added to a soln. of ammonia or ammonium carbonate, white mercuric amidochloride is precipitated, and a white turbidity is produced if only

1 : 200000 is present. The presence of traces of potassium carbonate makes the reaction even more sensitive. The reaction was examined by P. Einbrodt, A. Schöyen, C. Rehsteiner, G. C. Wittstein, and A. Ferraro.

19. The Constitution of the Ammonium Compounds and the Ammines

> A body possessing so many interesting properties as ammonia, standing as it were on the confines of mineral and of organic chemistry, and forming the connecting link between them, must even, on its own account, and still more from the remarkable variety of classes of combinations into which it enters, occupy a prominent place in the general theory of chemistry.—R. J. KANE.

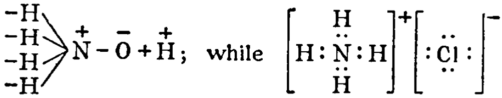
It seems as if tervalent nitrogen in ammonia, NH_3, changes into quinquevalent nitrogen in forming ammonium chloride, NH_4Cl. F. A. Kekulé[1] rigidly adhered to the doctrine of fixed valency, and the ready dissociation of ammonium chloride into ammonia and hydrogen chloride led him to assume the existence of what he designated *molecular compounds*, and to reject the hypothesis of a quinquevalent nitrogen atom in the ammonium compounds. He applied the term *atomic compounds* to those compounds in which all the atoms of the elements are united in such a way that their valencies are saturated. " These," said F. A. Kekulé, " are the true chemical molecules, and the only ones which can exist in the gaseous state." He assumed that the atoms of different molecules could attract one another so as to produce a kind of coupling of the molecules, and the coupled molecules were called molecular compounds, and symbolized accordingly thus, ammonium chloride becomes $NH_3.ClH$, etc. The nature of the atoms of the copulated molecules may be such that double decomposition is not possible, and "the two molecules, so to speak, adhere and form a group endowed with a certain amount of stability, which is always less than that of atomic combination." In other words, F. A. Kekulé assumed that molecular compounds are formed by direct addition of two or more simple mols., and the simple mols. retain to some extent their individuality, for they can be readily separated from one another apparently unchanged. F. A. Kekulé cited as examples of molecular compounds: ammonium salts, phosphorus pentachloride, iodine trichloride, crystalline salts which furnish anhydrous salt and water, etc. The compounds of silver chloride and ammonia, ferrous sulphate and nitric oxide, etc., can be added to the list. To sum up F. A. Kekulé's position: in order to make the theory of constant valency compatible with the existence of more complex molecules, it was assumed that these molecular compounds belonged to a different type of combination. These molecular compounds formed a miscellaneous group to which everything was relegated which did not fit the arbitrary hypothesis of constant valency, and it included many of the higher chlorides, higher oxides, double chlorides, hydrated compounds like the alums, etc.

The ammonia-radicle theory.—The oldest hypothesis concerning the nature of the ammonia-compounds, and that adopted by A. L. Lavoisier, supposed ammonia to be an independent base or radicle, saturating acids, and forming salts. This theory has been likened to the etherin theory of J. B. A. Dumas and P. F. G. Boullay. The radicle is NH_3; sal-ammoniac is NH_3+HCl; etc. The theory makes no attempt to explain the nature of the other classes of ammonia-compounds; nor does it explain the relation of ammonia to ordinary bases, which are metallic oxides, nor the differences between the ammoniacal salts from metallic salts of the same acid. Later on, the theory became associated with the mol. compound theory, so that sal ammoniac was represented by F. A. Kekulé as an associated complex of ammonia and hydrogen chloride, in which the ammonia remained tervalent. These compounds were considered to be analogous to double salts, and to substances with water of crystallization. This view was supported by the ready dissociation of sal ammoniac by heat—a subject discussed in connection with ammonium chloride (**2**. 20, 16). H. Rose also emphasized the analogy between compounds of ammonia and of water in various salts as exemplified by the use of the term ammonia of crystallization.

The amide theory.—In the amidogen theory of H. Davy, J. von Liebig, and R. J. Kane, ammonia is supposed to be compounded of a univalent radicle, NH_2, which he called amidogen; ammonia is regarded as *amidogen hydride,* or *hydrogen amidide or amide,* $NH_2.H$; and, added R. J. Kane, hydrogen amidide can fulfil the same functions as water—*i.e.* hydrogen hydroxide, $H.OH$—both as basic water and as water of crystallization. Sal ammoniac is hydrogen chloroamidide, $NH_2.H+HCl$; if chlorine could be abstracted from sal-ammoniac, the residue would be hydrogen subamidide as when by removing chlorine from white precipitate, mercury subamidide is formed (**4**. 31, 14). The amide theory has been likened to the acetyl theory of H. V. Regnault, and J. von Liebig.

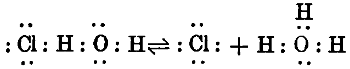
The ammonium theory.—In the ammonium theory of H. Davy, A. M. Ampère, and J. J. Berzelius, it was assumed that the ammonium compounds contain a metallic radicle, NH_4 (**4**. 31, 38), which may replace potassium, sodium, etc., in different salts. When ammonia unites with hydrogen chloride, the NH_4-radicle is formed which unites with chlorine to form ammonium chloride in the same way that potassium united with chlorine forms potassium chloride. The ammonium theory thus corresponds with the ethyl theory of J. J. Berzelius, and J. von Liebig. The nitrogen is assumed to be quinquevalent, and this is in harmony with the work of V. Meyer and M. T. Lecco, A. Ladenburg, and W. Lossen on the quaternary ammonium bases, and with the isomorphism of the ammonium and the potassium salts.

There is a difficulty in explaining the union of hydrogen chloride and ammonia on the ammonium theory: $NH_3+HCl=NH_4Cl$, because the reaction is attended by the evolution of a considerable amount of heat: $NH_{3gas}+HCl_{gas}=NH_4Cl_{solid}+42$ Cals. The separation of hydrogen chloride into its constituent elements is attended by the absorption of a considerable amount of heat—about 287 Cals.—and the union of chlorine and hydrogen with nitrogen is presumably attended by the evolution of a small amount of heat so that it might have been anticipated that the reaction would be endothermal. As M. E. Chevreul said, it is difficult to see how the feeble affinity of chlorine for nitrogen can overcome its powerful affinity for hydrogen. A. Wurtz, and L. Meyer consider the difficulty may be overcome by assuming that the affinity of chlorine for hydrogen is satisfied by the attraction it exercises in *all* the atoms of hydrogen within the molecule of ammonium chloride. H. Remy discussed the structure of the ammonium radicle; and H. Henstock gave for the electronic structure of the hydroxide:



was given by G. W. F. Holroyd for ammonium chloride. The subject was also discussed by E. B. R. Prideaux, and F. Hund. M. L. Huggins made estimates of the interatomic distances of the atoms in the ammonia molecule.

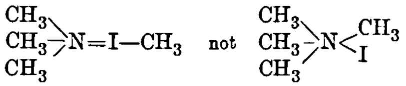
T. M. Lowry represented the strong acidity developed when, say, hydrogen chloride is mixed with water by assuming that the reaction can be symbolized $HCl+H_2O\rightleftharpoons Cl'+OH^{\cdot}{}_3$, which, expressed in terms of the electron theory of atomic structure, means that the hydrogen nucleus does not readily attach itself to an octet too fully occupied by other atoms to leave room for an additional nucleus; the water provides the required acceptor for the hydrogen nucleus, and the ionization of the acid involves the transfer of a portion from one octet to another:



$$:\overset{\cdot\cdot}{\underset{\cdot\cdot}{Cl}}:H:\overset{\cdot\cdot}{\underset{\cdot\cdot}{O}}:H\rightleftharpoons :\overset{\cdot\cdot}{\underset{\cdot\cdot}{Cl}}: + H:\overset{\overset{H}{\cdot\cdot}}{\underset{\cdot\cdot}{O}}:H$$

meaning that the ionized acid is really an ionized oxonium salt. In the case of bases, T. M. Lowry assumes that the real function of a base is that of an acceptor of hydrogen ion. Thus, $NH_3+H^{\cdot}\rightleftharpoons NH_4$. If the base is sufficiently strong, it may not only accept the hydrogen nuclei driven from the moleules of an acid: $NH_3+H^{\cdot}\rightleftharpoons NH_4$, but it may take them from compounds like water in which they are only weakly held: $NH_3+HOH\rightleftharpoons NH^{\cdot}{}_4+OH'$, so that the strength of the base is manifested by the liberation of hydroxyl ions. Measurements of the OH'-ions show that their concentration in a soln. of ammonia in water is small; and hence ammonium hydroxide is regarded as a weak base, so weak, indeed, that there can be no question of ammonium competing with the alkali metals in basic strength. On the other hand, suppose that the salts of an unknown basic radicle were being examined, and the properties of these salts had all the properties of the ammonium salts, as R. M. Caven has pointed out, it would undoubtedly be assumed that the ammonium radicle is comparable with the alkali metals in basic strength. The physical measurements of the conc. of the OH'-ions, however, do not show whether the compound formed by ammonia and water is ionizable or not; nor whether the compound is NH_4OH, or $NH_3.H_2O$. T. M. Lowry assumes that NH_3 and not NH_4OH is the base; and that the course of the reaction is $NH_3+H^{\cdot}+OH'\rightleftharpoons NH^{\cdot}{}_4+OH'$ and not $NH_3+H_2O\rightleftharpoons NH_4OH$, followed by $NH_4OH\rightleftharpoons NH^{\cdot}{}_4+OH'$. R. M. Caven showed that both hypotheses explain equally well the properties of soln. of ammonia and of ammonium salts, whereas T. M. Lowry's hypothesis accounts for the properties of the solid ammonium salts in containing the strongly basigenic though unstable ammonium radicle. This subject was also discussed by A. E. C. Smith, H. S. C. Briggs, V. A. Izmailsky, H. Remy, T. S. Moore, etc.

H. E. Armstrong emphasized the inadequacy of the ammonium theory to account for the extraordinary stability of tetramethylammonium iodide, $(CH_3)_4NI$, towards the strongest caustic alkali, and showed that the halogen compound behaves more like an alkyl iodide than ammonium iodide. Hence, it was inferred that the halogen is not simply associated with the nitrogen, but is rather retained and protected or masked by combination with a hydrocarbon radicle. The idea can be illustrated graphically:



$$(CH_3)_3{\equiv}N{=}I{-}CH_3 \quad \text{not} \quad (CH_3)_3{\equiv}N{<}{}^{CH_3}_{I}$$

Following up this idea, J. C. Cain represented the ordinary ammonium salts by formulæ like $H_3N{=}Cl{-}H$ for ammonium chloride, NH_4Cl; and $H_3N{=}O{=}H_2$ for ammonium hydroxide, NH_4OH, in which tervalent halogen and quadrivalent oxygen atoms are postulated. Similarly, ammonium sulphate, $(NH_4)_2SO_4$, becomes $H_3N{=}O(H){-}SO_2{-}O(H){=}NH_3$; ammonium hydrosulphide, NH_4HS, becomes $H_3N{=}S{=}H_2$—sulphur quadrivalent; and ammonium sulphide, $(NH_4)_2S$, becomes $(H_3N){\equiv}S{=}H_2$. The ionization of ammonium salts is usually symbolized $NH_4Cl \rightleftharpoons NH^{\cdot}_4+Cl'$, and is explained, on this hypothesis, by assuming there is first a dissociation $H_3N:ClH \rightleftharpoons NH_3+HCl$, followed by an ionization of the acid, $HCl \rightleftharpoons H^{\cdot}+Cl'$, and a union of NH_3 with the hydrogen ion to form a complex $NH_3.H^{\cdot}$, thus $NH_3+H^{\cdot} \rightleftharpoons NH_3.H^{\cdot}$. There is nothing in the evidence to distinguish between $NH_4^{\cdot}$ and $NH_3.H^{\cdot}$.

The isomeric optically active substituted ammonium salts which have been reported by organic chemists are not readily explained by an ammonium theory such as has been wrongly assumed to have been established by the experiments of V. Meyer and M. T. Lecco—*vide supra.* J. C. Cain argued from the above hypothesis of the constitution of the ammonium compounds that the optical activity is the result of a similar spatial configuration as that assumed for the carbon compounds where the quadrivalent nucleus, say NCl'''', instead of quadrivalent carbon, is at the centre of a tetrahedron so that

corresponds with

J. C. Cain similarly extends the idea to the phosphonium, $H_3P{=}ClH$; the arsonium, $H_3As{=}ClH$; the stibonium, $H_3Sb{=}ClH$; the sulphonium, $H_2S{=}ClH$; the oxonium, $H_2O{=}ClH$; and the diazonium, $C_6H_5{-}N{<}{}^{\equiv N}_{Cl}$, compounds.

According to F. Reitzenstein, the platinum-ammonia compounds, on account of their stability and characteristic behaviour, form perhaps the best defined series among the whole of the metal-ammonia compounds, and they serve as a typical model for the study of the others. G. Magnus' observations: *Ueber einige neue Verbindungen des Platinchlorürs,* in 1828, form the starting-point of a number of important studies on the compounds of ammonia with the platinum salts—*e.g.* by J. Gros, R. J. Kane, J. Reiset, M. Peyrone, M. Raewsky, S. M. Jörgensen, A. Werner, and many others. J. J. Berzelius suggested the first theory of their constitution. He supposed they are *gepaarte Verbindungen* in which the ammonia cannot be neutralized by an acid, and is without influence on the saturation capacity of the base. The so-called J. Reiset's first chloride was symbolized $Pt.\overline{NH_2.NH_4Cl}$ by J. J. Berzelius, and this translated into modern symbols is equivalent to the formula $Cl.NH_2(NH_4).Pt.NH_2(NH_4).Cl$, where $Pt(N_2H_4)$ is supposed to be paired with $N_2H_8Cl_2$. The doctrine of union by the pairing or copulation of mols. rested on C. F. Gerhardt's *corps copulés,* and it gradually came to be identified with chemical combination (**1.** 5, 16).

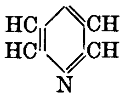
C. F. Gerhardt referred the platinum bases to the ammonia type in which different atoms of hydrogen were replaced by platinum or ammonium, NH_4. The hypothesis assumed many different guises, as is illustrated by the different formulæ proposed by A. W. Hofmann, C. Weltzien, J. G. Gentele, W. Odling, H. Kolbe, H. von Euler, for any particular compound, say, J. Reiset's first chloride. C. F. Gerhardt gave $N_2H_5Pt.HCl$; A. W. Hofmann, $H_4Pt(NH_4)_2N_2Cl_2$; C. Weltzien, $N_2\{H_4(NH_4)_2Pt\}Cl_2$; W. Odling, $Pt(N_2H_5)_2.2HCl$; H. Kolbe, $[\{Pt(NH_3)_2\}H_6]N_2Cl_2$; etc. The various explanations based on the substitution of hydrogen in ammonia by ammonium was designated as " unscientific play which serves no useful purpose." The compounds concerned were also assigned systematic names consonant with the particular hypothesis employed in building their constitutional formulæ. As a result some of the longest known ammonio-metal bases and salts have half-a-dozen different systematic names. Thus, J. Reiset's first base, $Pt(OH)_2.4NH_3$, was called *platodiammonium oxyhydrate* by C. W. Blomstrand, *platodiamminihydrate* by P. T. Cleve, *diplatosamine* by C. F. Gerhardt, *ammonplatammonium oxyhydrate* by C. Grimm, *platinous tetramminohydroxide* by A. Werner. In W. Odling's system, the platinous and platinic compounds were each divided into two groups, one group contained the amine NH_2-radicle, and the other the univalent group N_2H_5, that is, $NH_2.NH_3$, called the ammonamine radicle. Thus J. Reiset's first chloride was represented $Pt(NH_2)_2.2HCl$ and M. Peyrone's chloride $Pt(N_2H_5)_2.2HCl$.

C. E. Claus, in his work *Beiträge zur Chemie der Platinmetalle* (Dorpat, 1854), rejected the ammonium theory as an explanation of the constitution of the metal-ammonias, and he advocated the older formulæ which regarded these compounds as products of the union of the metal oxide with ammonia and an acid. He was in a difficulty in explaining how the characteristic properties of ammonia are so masked that the ammonia cannot be detected by the usual reagents, and he postulated that in the ordinary ammonium compounds the ammonia is in an active state, while in the metal-ammonias it is passive. This hypothesis, said C. Weltzien, explains nothing; it can never be accepted by chemists because every atom in a compound must exercise an influence on the properties of the whole complex. C. E. Claus adopted a modified form of J. J. Berzelius's theory of copulated compounds, but instead of representing J. Reiset's first chloride, with J. J. Berzelius, as $Pt\{NH_2(NH_4)Cl\}_2$, he represented it as a compound of ammonia with platinous chloride, namely, $(NH_3)_4PtCl_2$. This view was still further modified by C. W. Blomstrand, and S. M. Jörgensen. It was assumed that ammonia molecules can unite together in chains like the dyad CH_2-groups unite in chains to form homologous series of hydrocarbons. For instance:

$$Pt{<}\begin{matrix}NH_3—NH_3—Cl\\NH_3—NH_3—Cl\end{matrix}$$

$$\begin{matrix}Cl\\Cl\end{matrix}{>}Pt{<}\begin{matrix}NH_3—NH_3—Cl\\NH_3—NH_3—Cl\end{matrix}$$

S. M. Jörgensen investigated the chloro- and the bromo-pentamminocobaltic salts, $CoCl_3.5NH_3$ and $CoBr_3.5NH_3$, and found that in each series one of the halogen atoms is related to the whole complex differently from the other two. For example, (i) One hydrogen atom remains associated with the cobalt and ammonia while the other two can be replaced by double decomposition with, say, silver nitrate; (ii) Conc. sulphuric acid displaces two halogen atoms per mol., but does not attack the third halogen atom. In order to show that one halogen atom is associated with the cobalt and ammonia differently from the other two halogen atoms, the formulæ of these compounds can be written, $(Co,Cl,5NH_3)Cl_2$ and $(Co,Br,5NH_3)Br_2$. S. M. Jörgensen further assumed that the NH_3-groups enclosed in the brackets are either united as a normal chain, $—NH_3—NH_3—$, or as a forked chain, $NH_4—NH_2<$. Pyridine, NC_5H_5, is constituted:

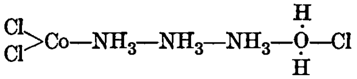


and can take the place of ammonia in these compounds, the resulting products are in every way analogous with the metal ammonias. If, therefore, the metal-ammonia bases are derived from NH_4 by replacing hydrogen by NH_4-groups, the substituted hydrogen atoms must be directly bound to the nitrogen atom. The existence of the pyridine compounds shows that this assumption is not necessary, and hence, S. M. Jörgensen considered it to be unlikely that the metal-ammonias contain the ammonium group. Further, in order to explain why one of the halogen atoms does not react like the other two, S. M. Jörgensen assumed that those atoms which are directly attached to the metal atom are masked and do not respond to the solicitations of chemical reagents in the normal way, while the halogen atoms which are terminal members of the ammonia chains behave quite regularly. Thus, S. M. Jörgensen represented the two cobalt salts under discussion by the formulæ:

$$\mathrm{Cl{-}Co}\left\langle\begin{matrix}\mathrm{NH_3{-}Cl}\\ \mathrm{NH_3{-}NH_3{-}NH_3{-}NH_3{-}Cl}\end{matrix}\right.$$

$$\mathrm{Br{-}Co}\left\langle\begin{matrix}\mathrm{NH_3{-}Br}\\ \mathrm{NH_3{-}NH_3{-}NH_3{-}NH_3{-}Br}\end{matrix}\right.$$

and in cases where a water-molecule replaces one of ammonia, he assumed that this is linked up with the ammonia chain in virtue of the quadrivalency of oxygen. For example, the compound $CoCl_3.3NH_3.H_2O$ in which two of the halogen atoms are masked while the third behaves in the normal manner, was represented by the formula



$$\left.\begin{matrix}\mathrm{Cl}\\ \mathrm{Cl}\end{matrix}\right>\mathrm{Co{-}NH_3{-}NH_3{-}NH_3{-}}\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{O}}}\mathrm{{-}Cl}$$

According to this hypothesis, the compound $PtCl_2.4NH_3$ is represented by $Pt{=}(NH_3.NH_3.Cl)_2$. The principal weakness of this view of the constitution of the ammines rests on the apparent absence of limitation to the possible number of ammonia groups which might be linked up into chains. In the great majority of cases, a metal atom can hold no more than six ammonia groups, often four, and seldom any other number. The next important contribution to this subject was made by A. Werner. The attempt to distinguish mol. from atomic compounds by structural formulæ based upon ordinary valencies deduced from the manifestations of the simple "atomic compounds," has not been successful. Some of the elements involved in the formation of the mol. compounds appear to manifest higher valencies than the numbers deduced from the simpler, more numerous, and more stable compounds. A. Werner's hypothesis seems to give a clearer insight into the constitution of double salts, complex salts, crystalline hydrates, etc., than any yet propounded; and it forms the most elegant system yet proposed for classifying large groups of complex compounds, and particularly the ammonia metal bases. Although it is fully recognized that this hypothesis has not assumed its final form, yet, as one of the fathers of philosophy has said, we begin with doubts in order that we may end with certainties; and there is the promise that the conception of mol. compounds as something specifically distinct from atomic compounds will ultimately be banished from chemistry.

Valency can be regarded as a measure of the capacity of an atom for combination with hydrogen equivalents of atoms; it is considered to be negative in combination with electropositive atoms, and positive in combination with electronegative atoms. Hypotheses have been suggested at various times, ranging from that of C. L. le Sage in 1764 to that of J. H. van't Hoff in 1881, which postulate a pre-existing force, acting in a definite direction or directions determined by the structure or rather the shape of the atom. According to C. E. Claus, the hypothesis that the valency of multivalent atoms is a pre-existing force acting with definite units of affinity is as unfounded as it is unnecessary. C. L. Berthollet recognized that there are predominant affinities in substances which are the source of their characteristic properties; and there are others which are inferior to these, but which nevertheless give rise to several remarkable phenomena. The same idea was propounded by J. Mercer, and L. Playfair. According to A. Werner, when the combining capacity of an atom, as defined empirically by the theory of valency, is exhausted, the atoms still possess a " particular kind of affinity," which enables them to form mol. complexes, corresponding with J. J. Berzelius' " compounds of higher orders " (**1.** 2, 10). S. U. Pickering, A. Wurtz, and H. E. Armstrong employed the term **residual affinity** for the affinity which remained after the ordinary valency of an element had been satisfied. In other words, **simple or primary molecules may possess a residual affinity which enables them to unite together and form more complex stable compounds.** Thus, the sulphur atom in sulphur trioxide ; the oxygen atom in water ; the chlorine atom in hydrogen chloride ; the nitrogen atom in ammonia ; the gold atom in auric chloride ; the platinum atom in platinic chloride, etc., all possess residual affinity which permits these molecules to unite additively with other molecules. The residual affinity or residual valency is not measured in terms of hydrogen equivalents, but in terms of the number of atoms bound in the molecule in excess of those which are associated by the operation of the normal exchange of valencies ; it seems to depend not on one atom alone but on the nature of all the atoms present in a particular molecule. Residual affinity appears to play a *rôle* similar to ordinary chemical affinity, but the new manifestation of valency in compounds differs from that which occurs with the radicles. For instance, **residual affinity does not lead to the combination of univalent radicles as defined by the doctrine of valency.** In illustration, water, H_2O ; antimony pentachloride, $SbCl_5$; sulphur tetrachloride, SCl_4 ; phosphorus oxychloride, $POCl_3$; phosphorus pentachloride, PCl_5 ; hydrogen cyanide, HCy ; ammonia, NH_3 ; etc. ; may be regarded as compounds in which the primary valencies of the elements are exhausted, and yet, in virtue of their residual affinity, readily form compounds like $SbCl_5.4H_2O$; $SbCl_5.3HCy$; $SbCl_5.PCl_5$; $SbCl_5.POCl_3$; etc. A. Werner draws no sharp distinctions between the union of P_2O_5 and Na_2O to form Na_3PO_4, and between $BaCl_2$ and H_2O to form $BaCl_2.2H_2O$. This does not mean that the mode of action of the two kinds of affinity is different, since both are in many ways similar. " Nevertheless," says A. Werner, " it appears at present desirable to preserve the difference because the doctrine of valency is yet in a transitional stage, and hence it is judicious to construct sharply defined concepts." A. Werner assumes that complex molecules consist of a core or inner sphere consisting of a group of atoms directly combined or coordinated by primary valencies with a central atom ; and an outer sphere or shell holding a definite number of atoms or groups of atoms in combination by the exercise of secondary valencies. The group of atoms and radicles in the inner sphere is generally represented with thin square brackets, those on the outer sphere are put outside the square brackets—*e.g.* $[PtCl_6]K_2$; $[CoF_4(OH)_2]K_2$; etc. Accordingly, A. Werner, more or less vaguely, distinguishes two kinds of valency :

1. **Chief or primary valency.**—*Hauptvalenz*—which represents those manifestations of chemical affinity which enable the combining capacities (valencies) of the elements to be expressed in terms of hydrogen atoms or their equivalents, *e.g.* Cl—, Na—, NO_2—, CH_3—, . . . The forces emanating from the central atom mainly determine the grouping of the atoms in the central core of complex compounds, although, of course, the mutual attractions of the associated atoms or radicles must be considered.

2. **Auxiliary or secondary valency.**—The conception of auxiliary valencies lies at the base of Werner's theory, but the conception is vague enough to be adaptable to requirements as particular cases arise. *Nebenvalenz*—which represents those manifestations of residual chemical affinity which are able to bring about the stable union of certain molecules as if the molecules were themselves radicles able to exist as independent molecules, *e.g.* H_2O—, NH_3—, HCl—, $CrCl_3$—, . . . The secondary valency is not to be confused with residual affinity nor with J. Thiele's partial valencies —*Partialvalenzen*—because it is determined by the mutual attractions exerted by the atoms or radicles in the central core ; these are known to possess considerable residual chemical affinity, and they have the greatest tendency to form hydrated and

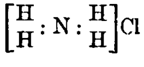
ammoniated complexes with the salts of the metals. However, there is probably no essential difference in the forces active in forming compounds exhibiting the two kinds of valency ; the actual difference is one of degree not of kind in the same sense that a millimetre differs from a metre ; or in the same way that the forces concerned with ordinary and residual affinity are the same in kind but not in quantity. Consequently, in many cases the distinction between principal and auxiliary valencies cannot be maintained.

The force concerned in the formation of compounds is supposed by A. Werner to be distributed over the surface of the atom, and to be utilized in binding a sufficient number of atoms to form an enclosing shell—A. Werner's inner sphere—about the central attracting or co-ordinating atom. When the binding capacity of an elementary atom (primary valency) appears exhausted, A. Werner assumes that the atom can still link up with other molecules (secondary valency), and build more complex molecules. There is, however, a limit to the binding capacity of both primary and secondary valencies. **The maximum number of atoms, radicles, or molecular groups—independent of their valencies—which can be directly linked or co-ordinated with a central atom is called the co-ordination number.** The co-ordination number of an atom can be determined from compounds in which the maximum number of atoms, radicles, or mol. groups, linked with a central atom, are known. The co-ordination number of most atoms, curiously enough, is six ; in many cases it is four—particularly with elements of small at. wt. like lithium, beryllium, carbon, boron, and nitrogen, or elements of high at. wt. like gold, mercury, thallium, and bismuth ; and with molybdenum and the addition products of the chlorides of the alkaline earths, the co-ordination number appears to be eight, *e.g.*

$$[Pt(NH_3)_4]Cl_2 \qquad [Co(NO_3)_6]R_3 \qquad [Ca(NH_3)_8]Cl_2$$

The fact that the co-ordination number for so many elements is six, and is generally independent of the nature of the co-ordinated groups, has made A. Werner suggest that the number is decided by available *space* rather than affinity, and that six is usually the maximum number which can be fitted about the central atom to form a stable system. Consequently, the co-ordination number represents a property of the atom which enables the constitution of " molecular compounds " to be referred back to actual linkings between definite atoms. A molecular compound is primarily formed through the agency of secondary valencies ; and, just as primary valencies determine the number of univalent atoms or their equivalent which can be linked to a central atom, so secondary valencies determine the number of mols. which can be attached to the central atom. The secondary valency is often active only towards definite mol. complexes, and hence the formation of additive compounds with other mol. complexes does not occur. Accordingly, the number of secondary valencies which are active towards different molecules is not always the same.

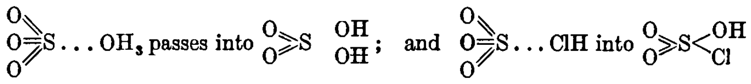
When it is desired to emphasize the distinction between primary and secondary valencies, A. Werner recommends using a continuous line for the former, and a dotted line for the latter. The nitrogen atom of ammonia, NH_3, has an unsaturated secondary valency, and the hydrogen or chlorine atom in hydrogen chloride, HCl, has likewise an unsaturated secondary valency. The formation of ammonium chloride is therefore illustrated by the scheme : $H_3N+HCl=H_3N\ .\ .\ .\ HCl$. The dotted line represents the auxiliary valency joining the hydrogen atom of HCl with the nitrogen atom of NH_3. The co-ordination number of the nitrogen atom is here 4. It is not likely that one of the hydrogen atoms in ammonium chloride is " linked with a greater amount of affinity than the other three," and very probably there is a state of equilibrium in which the affinity is distributed over all the hydrogen atoms, and a complex radicle is formed in which each of " the four atoms of hydrogen is united to the nitrogen by the same amount of affinity." Hence, A. Werner writes the structural formula of ammonium choride :



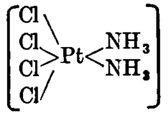
$$\left[\begin{matrix}H\\H\end{matrix}:N:\begin{matrix}H\\H\end{matrix}\right]Cl$$

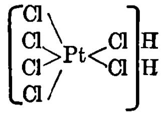
The practice of assuming an increased valency for nitrogen when ammonia unites with hydrogen chloride, says A. Werner, if consistently carried out, would make antimony tervalent in antimony trichloride, and quinquevalent in $SbCl_3.KCl$, etc. Bivalent iron in ferrous cyanide, $FeCy_2$, would become decivalent in potassium ferrocyanide, K_4FeCy_6. J. Piccard and J. H. Dardel, and P. Pfeiffer discussed this subject.

The formation of sulphuric and chlorosulphuric acids by the union of sulphur trioxide with water and hydrogen chloride respectively is brought about by the secondary valencies as indicated in the schemes: $O_3S+OH_2=O_3S \ldots OH_2$; and $O_3S+ClH=O_3S \ldots ClH$. *When one of the reacting molecules contains double-linked atoms, the auxiliary valencies may not be sufficiently strong to preserve the integrity of the new mol., and the atoms of the addition product may be rearranged.* For example, this is the case with sulphur trioxide. Thus:

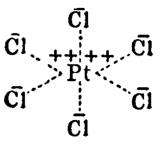


The change in the type of the compound is due to an intra-molecular rearrangement, but such a change may not occur if the secondary valency is sufficiently strong and the addition product is stable. What has been suggested appears to be applicable with the analogous reaction: $Cl_4Pt+2NH_3=Cl_4Pt \ldots (NH_3)_2$; and $Cl_4Pt+2KCl=Cl_4Pt \ldots (ClK)_2$. A. Werner represents the two latter compounds by the respective formulæ: $[Pt(NH_3)_2Cl_4]$, and $[PtCl_6]K_2$. All four chlorine atoms can be removed from the first compound without disturbing the ammonia mols., and consequently the chlorine atoms do not act as intermediate links binding the NH_3 mols. to the platinum, as they would in, say, $Cl_2Pt(Cl.NH_3)_2$. It is therefore inferred that the NH_3 mols. are directly attached to the platinum atom. Again, no difference has been detected in the chemical behaviour of the four chlorine atoms. This would not be the case if the two ammonia molecules were intermediate links between two of the chlorine atoms, and the central atom of platinum, as would be the case in, say $Cl_2Pt(NH_3.Cl)_2$. Hence, in all probability, the six groups are all attached directly to the platinum. Consequently, A. Werner writes:

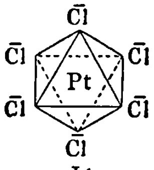




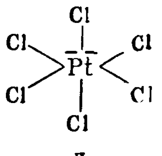
The latter formula has been established in a manner similar to the former. A. Werner assumes that four of the chlorine atoms are attached to platinum by principal valencies, and two by auxiliary valencies; and that the last two chlorine atoms are not saturated so that the hydrogen atoms may attach themselves at these points. T. M. Lowry modified the idea by assuming that the quadrivalent platinum atom begins by attracting to itself a shell of six chlorine ions as in I*a* of the following schemes where the electrostatic attractions or electrovalencies are represented by dotted lines. The orientation of these six ions is identical with that of the six chlorine ions distributed about each ion of sodium in a crystal of sodium chloride—I*b*. The outer shell



I*a*



I*b*



II

of 32 electrons is completed by drawing a pair of electrons from each of the six chlorine ions. These six duplicates are held in common by platinum and chlorine, each element claiming an equal share. The platinum therefore gains six electrons, and each chlorine atom loses one. The result of this transfer is illustrated above by formula II. The bivalent ion, $PtCl_6$, so formed contains six neutral chlorine atoms held by co-valencies, and the double negative charge is held by the atom of platinum. The platinum atom is entirely surrounded by chlorine, and in the non-ionized potassium salt, the orientation of the two potassium atoms is determined by crystallographic considerations of close-packing. The electronic structure was discussed by L. C. Jackson, D. M. Bose, L. A. Welo and A. Baudisch, N. V. Sidgwick, and B. Cabrera.

A study of the platinum-ammines shows that a large number of them can be arranged in two well-defined series. One series is derived from platinic chloride, $PtCl_4$; and the other from platinous chloride, $PtCl_2$. The co-ordination number of the former is six; and the latter, four. Thus, with ammonia and chlorine as the acidic radicle in the complex,

I. *Platinum-ammines derived from platinous chloride*—$PtCl_2$.

	Werner's formula.	Old formula.
1. Tetrammineplatinous chloride . . .	$[Pt(NH_3)_4]Cl_2$	$PtCl_2.4NH_3$
2. Chlorotriammineplatinous chloride . . .	$[Pt(NH_3)_3Cl]Cl$	$PtCl_2.3NH_3$
3. Dichlorodiammineplatinum (two isomers) . .	$[Pt(NH_3)_2Cl_2]$	$PtCl_2.2NH_3$
4. Potassium trichloroammineplatinite . . .	$[Pt(NH_3)Cl_3]K$	$PtCl_2.KCl.NH_3$
5. Potassium tetrachloroplatinite. . .	$[PtCl_4]K_2$	$PtCl_2.2KCl$

2. Chloropentammineplatinic chloride . .	$[Pt(NH_3)_5Cl]Cl_3$	$PtCl_4.5NH_3$
3. Dichlorotetrammineplatinic chloride . .	$[Pt(NH_3)_4Cl_2]Cl_2$	$PtCl_4.4NH_3$
4. Trichlorotriammineplatinic chloride . . .	$[Pt(NH_3)_3Cl_3]Cl$	$PtCl_4.3NH_3$
5. Tetrachlorodiammineplatinum (two isomers) .	$[Pt(NH_3)_2Cl_4]$	$PtCl_4.2NH_3$
6. Potassium pentachloroammineplatinate . .	$[Pt(NH_3)Cl_5]K$	$PtCl_4.KCl.NH_3$
7. Potassium hexachloroplatinate . . .	$[PtCl_6]K_2$	$PtCl_4.2KCl$

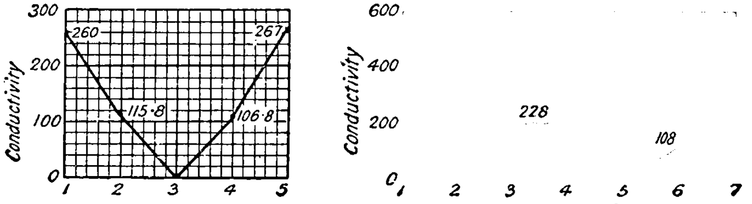
The simple or compound radicles which form the complex represented within the square brackets, are supposed to be directly united with the central atom of platinum. The complex takes part in chemical reactions as if it were one individual radicle. The substituted ammonias, methylamine, propylamine, water, hydroxylamine, pyridine—symbolized *py*—aniline, toluidine, ethylenediamine, $NH_2.CH_2.CH_2.NH_2$—symbolized *en*—phosphine, arsine, stilbine, mercaptan, etc. can take the place and function like ammonia without altering the type. The substitution may be partial or complete. In the case of hydroxylamine, the reducing action prevents the formation of platinic salts, and only the platinous salts have been made—*e.g.* $[Pt(NH_2OH)_4]Cl_2$; $[Pt(NH_3)_2(NH_2OH)_2]Cl_2$; $[Pt(NH_2OH)_2Cl_2]$; etc. In the case of ethylenediamine, one molecule replaces two molecules of ammonia. The acidic radicle in the complex can be replaced by acidic radicles—Cl, Br, NO_3, CO_3, SO_4, OH, Cy, SCy, etc.; and if the basic radicle ammonia or its eq. in the complex is replaced by an acidic group, the complex becomes acidic instead of basic and the platinic ammine complexes finally pass from electro-negative (basic) radicles to electropositive (acidic) radicles. Potassium chloroplatinate is the end-member of the series of platinic ammines and potassium chloroplatinite is the terminal member of the series of platinous ammines. It will be obvious that an enormous number of derivatives are conceivable.

Nomenclature of the metal ammines.—For a long time, the complex metal ammonia compounds were named after the discoverer or an investigator of the salt, or after some distinctive peculiarity, generally the colour—luteo—from *luteus*, brownish or orange-yellow; rosao—from *rosa*, rose-red; purpureo—from *purpura*, purple; praseo—from *πράσιος*, leek-green; flaveo—from *flavus*, golden-yellow; croceo—from *κρόκος*, saffron; xantho

—from ξανθός, yellow; violeo—from *viola*, violet; rhodeo—from ῥόδον, the rose. A. Werner's system of naming the metal-ammonia compounds has been almost universally adopted. The constituents of the complex are taken first; and of these, the acid radicles with the suffix "o" come first; then follow any groups which behave like ammonia, *e.g.* H_2O is called **aquo**; O.NO, **nitrito**, or NO_2, **nitro**; NO_3, **nitrato**; CO_3, **carbonato**; SO_3, **sulphito**; SO_4, **sulphato**; SCy, **thiocyanato**; etc. And lastly, preceding the metal itself, each ammonia molecule is designated an **ammine**, spelt with a double "m" to distinguish the word from the amines or substituted ammonias. The prefixes di, tri, . . . indicate the number of each. The whole is written as one word. Examples appear in the above list. T. Steche made some remarks on the nomenclature of A. Werner's system.

The valency of the complex is numerically equal to the difference between the ordinary valency of the central atom and the number of negative (acidic) elements or groups attached to the metal. Thus, the normal valency of platinum in the first of the above series is 4, hence the valency of $[Pt(NH_3)_5Cl]$, with one negative (acidic) group "Cl," will be 3; this means that the complex in question acts as a tervalent electropositive (basic) radicle; and it can unite with three univalent electronegative (acidic) radicles. The valency of $[Pt(NH_3)Cl_5]$ with five negative (acidic) groups, "Cl," will be —1. This means that the complex under consideration will act as a univalent electro-negative (acidic) radicle, and it can accordingly unite with one electropositive (basic) radicle like potassium, sodium, etc. If the valency of the acidic radicles in the complex is numerically equal to the normal valency of the central atom, the complex will be nullvalent. This is the case, for instance, with the complex $[Pt(NH_3)_2Cl_4]$.

The nullvalent ammine bases are non-electrolytes, they do not conduct electricity. In the other ammine bases the complex forms one ion which is either electropositive (basic), and therefore a cation, or else electronegative (acidic), and therefore an anion. During electrolysis, the components of the complex are not disturbed. The mol. conductivities of the ammine derivatives of $PtCl_2$ at 1000 litres dilution are indicated in Fig. 42; the conductivities of the derivatives of $PtCl_4$ are indicated in Fig. 43; the second derivative, $[Pt(NH_3)_5Cl]Cl_3$, is not known. The electrical conductivities of these compounds correspond with the ions obtained on electrolysis, as indicated by the formulæ in the above tables. The hydroxides are strong bases and in that respect resemble the caustic alkalies, for when boiled with ammonium salts they expel ammonia; they absorb carbon dioxide from the air to form carbonates or carbonato-compounds; they precipitate the hydroxides of aluminium, iron, etc., from solns. of their salts; and in the case of aluminium, the hydroxide is soluble in an excess of the base as is the case with caustic alkalies. The ammonia groups in the ammines are not attached in the "loose" way typified by the so-called ammonia of crystallization, but they are bound so firmly and intimately as to produce a complete change in the character of the salts. For example, the platinum is not precipitated from soln. of the ammines as sulphide by hydrogen sulphide; the ammonia is not expelled by potash or by chlorine; and the chlorine, presumably in the complex, is not precipitated by silver nitrate. As a matter of fact, the analytical reactions of each base are characteristic of the complex as a whole, and of the radicles associated with the complex—indicated outside

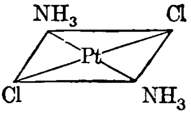


Platinochloroammines. Platinichloroammines.

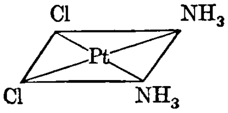
FIGS. 42 and 43.—The Electrical Conductivities of the Platinumchlorammine Derivatives. (The abscissæ refer to the numbers in the above tables.)

the square brackets in the above formulæ. Thus, with the cobalt ammines, cobalt tervalent, all the bromine in $[Co(NH_3)_6]Br_3$ is precipitated by silver nitrate; in $[Co(NH_3)_5Br]Br_2$ only two-thirds of the total bromine is precipitated by silver nitrate; in $[Co(NH_3)_4Br_2]Br$, only one-third of the total bromine is precipitated; and in $[Co(NH_3)Br_3]$ none of the bromine is precipitated.

M. Peyrone, and P. T. Cleve showed that there are two isomeric platinous diamminodichlorides; C. W. Blomstrand, P. T. Cleve, and S. M. Jörgensen consider that the difference can be represented graphically by $Cl.Pt.NH_3.NH_3.Cl$, and $Cl.NH_3.Pt.NH_3.Cl$. A. Werner believes that the isomerism is due to a difference in the spatial arrangement of the four radicles. If the four radicles be attached to a central platinum atom as if they were at the angular points of a regular tetrahedron, isomerism could not be expected because the four groups can be interchanged without altering their relations with one another. Hence it is inferred that the groups are arranged about the central atom of platinum in one plane. The resulting isomerism can be graphically illustrated by the schemes:



Trans-position.



Cis-position.

or by the more usual type of formulæ:

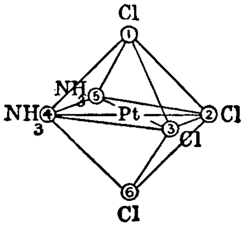
$$\begin{matrix}NH_3\\Cl\end{matrix}>Pt<\begin{matrix}Cl\\NH_3\end{matrix}$$

Trans-platinodichlorodiammine.

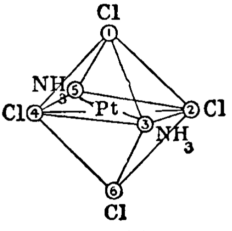
$$\begin{matrix}Cl\\Cl\end{matrix}>Pt<\begin{matrix}NH_3\\NH_3\end{matrix}$$

Cis-platinodichlorodiammine.

With platinic compounds having a co-ordination number 6, the six co-ordinated units in the complex appear to adopt some symmetrical arrangement, and to behave as if they were located at the six vertices of an imaginary regular octahedron described about the sphere of influence of the central atom. Thus, the two isomers of $[Pt(NH_3)_2Cl_4]$ can be represented by:



Cis-position.



Trans-position.

If the corners of the octahedral figure be always numbered 1 to 6 as shown in the diagram, the relative positions of the acidic or basic radicles can be indicated by numbers. Assuming that the diagrams correctly represent the relative position of the radicles, the cis-compound is called the 2·3-tetrachlorodiammineplatinum, and the trans-compound the 2·4-tetrachlorodiammineplatinum. The geometry of co-ordination was studied by R. Straubel, and G. F. Hüttig.

R. Abegg and C. Bodländer suggest that the stability of a complex depends upon the so-called electro-affinity of the ions, *i.e.* on the affinity of the radicles for electric charges or electrons. This can be approximately measured in terms of the electrolytic potential, on assumption that the unknown conc. of the free atoms in sat. soln. are the same for all elements. In a general way, the smaller the numerical value of the electrolytic potential (positive or negative) of a salt, the greater the tendency to form complex ions. In the further development of their theory, R. Abegg and G. Bodländer distinguish between what is called the atom or radicle affinity and electro-affinity. The stability of inorganic compounds depends not so much on the affinity of the atoms or radicles for one another as upon their affinity for electric charges. Sodium chloride, for instance, is said to be a stable compound, not so much because of the strong affinity between the atoms of chlorine and sodium as because a great deal of free energy must be expended in order to resolve the compound back into its elements—or, electrochemically speaking, to discharge the $Na^{\cdot}$ and Cl' ions. When the atom affinity between the two components of a compound is feeble, ionization can occur without the expenditure of much energy. On the other hand, salts like the mercury cyanide and halides are but little ionized in soln. because it is assumed the affinity of the atoms for one another is large enough to prevent much ionization. The electro-affinity of an ion for its charge is a constant, the atom affinity depends upon the particular elements in combination. Compounds formed by the union of elements with strong atom affinities have a tendency to form complex anions—*e.g.* $[HgI_4]''$, $[PtCl_6]''$, $[AuCl_3]'$, etc. In the formation of what A. Werner calls *Einlagerungscomplexe* or penetration complexes in a reaction of the type $MX_m+nA \rightarrow [MA_n]X_m$, where n is the co-ordination number of the metal, the anion X must, in general, be relatively feebly connected with the complex in what A. Werner calls the *zweite Sphäre*—the second or outer sphere—so that a great atom affinity between X and M would hinder the formation of such a complex cation but favour the formation of a complex anion.

It is not to be supposed that the heat of combination (meaning the free energy of combination) of two elements is a measure of their atom affinities. A difference in the composition of a series of solid salts (of the stronger acids) is often attended by eq. differences in the heats of formation so that the heat of formation appears to be an additive property. In the simplest cases (*e.g.* the halides), the heat of formation is the sum of contributions made by each component. Neglecting the small heats of ionization and solution, the heat of combination of simple salts will be the sum of the electro-affinities of each of the two ion-forming components, plus the atom affinity of the component elements ; and with complexes, yet a fourth term, the heat of formation of the uncharged complex must be added. Consequently, the strength of the union between two elements is not measured by the heat of combination alone. Often, indeed, the heat of combination of the elements with a relatively large affinity for one another is small. This is the case with compounds of the noble metals and their neighbours in the electrochemical series. For example, the behaviour of gold bromide on ionization suggests that the elements have a strong affinity for one another, whereas this salt readily gives off bromine when warmed, presumably because the heat of formation is small—nearly 9 Cals.

The thermal phenomena of neutralization and double decomposition are abnormal if a complex anion is formed. Abnormal heats of neutralization or deviations from the law of thermo-neutrality are characteristic of compounds with a high atom affinity. The halides of copper, silver, gold, cadmium, mercury, and platinum have small or anomalous ionization constants, and abnormal heats of formation. The heats of precipitation (the negative values of heats of soln.) of sparingly soluble, chemically analogous compounds were shown by J. Thomsen to be greater the less the solubility of the salt. A large heat of precipitation means that the heat of formation of the solids is relatively large. A low solubility may be regarded as a consequence of small ionization, and the two properties run parallel with sparingly soluble substances. Examples are thallous chloride, silver and lead halides, etc. The thermal data with the halogen (excepting fluorine), sulphur, nitrogen, and carbon compounds of gold correspond with a relatively large atom affinity so that salts of the halogen acids, thiosulphuric, sulphurous, thiocyanic, and hydrocyanic acids can exist in aq. soln. Salts of the oxygen acids—sulphates and nitrates—are almost completely hydrolyzed in aq. soln. The halides are protected from the same fate by the formation of complex anions, $[AuCl_4]'$.

$[AuCl_3OH]'$, etc.—the linkage between the metal and the acid radicle is not broken and virtually no gold ions are formed. If auric tetramminonitrate, $[Au(NH_3)_4](NO_3)_3$, be treated with potassium chloride, auric tetramminochloride, $[Au(NH_3)_4]Cl_3$, is probably first formed and, owing to the affinity between the outer sphere and the complex itself, ammonia is displaced and the series of auric amines, $[AuCl(NH_3)_3]Cl_2$, $[AuCl_2(NH_3)_2]Cl$, and $[AuCl_3NH_3]$, is produced. As a matter of fact, some of the combined chlorine passes out with the ammonia as ammonium chloride, and hydroxyl remains in the complex. This subject has been studied by F. Ephraim, A. Pieroni, E. Weitz, etc.

F. Ephraim found that about 80 per cent. of the 167 ammino-compounds he examined had the co-ordination numbers 2, 4, 6, and 8. The ammino-compounds fall into various classes according as the anion is included in the complex—the mol. ammines—or the cation is included in the complex; there are also the so-called double-shell ammines; the mixed compounds, etc. Comparing the physical properties of the ammines of the halides, it follows that (i) in the group of the alkali and alkaline-earth metals and magnesium, the affinities in the formation of the higher ammoniates are smaller the greater are the weight, at. vol., and electrolytic potential of the metal-ion, the more strongly negative and the smaller is the anion, and the greater the heat of formation and vol. concentration in formation of the salt. (ii) The iron group obeys the same rules, but the effects of the weight of the cation and vol. contraction are reversed. (iii) The copper, zinc, and lead compounds obey the same rule in some cases, but in others inverse rules. (iv) High m.p. and low solubility of the ammonia-free salt influence the stability of the ammoniates. The lattice structure derived from the X-radiograms indicates that in the hexammine-compounds of the halides of the iron metals, manganese, and zinc, the ammonia molecules are very closely packed, there being practically no free space in the metal-hexammine complex; the calculated spaces occupied by the halogen atoms are in agreement with those observed for normal polar binary compounds. The formation of the ammonia compound is in these cases accompanied by a separation of the metal from the halogen-ion, involving mechanical work, E, which may be calculated. The total heat of formation of the ammoniate involves this value, E, and the energy concerned in the association of the ammonia mols. with the cation, where E is small, *i.e.* where the cation and anion are already somewhat separated, as in the iodides, the ammoniate will be more stable for the same cation. The differences in affinity in the formation of the ammoniates are therefore bound up with space considerations; the instability of the ammoniates of the alkali metals, for example, depends not so much on the low energy involved in association of the cation with ammonia mols. as on the high value of E.

Crystalline magnesium chloride, $MgCl_2.6H_2O$, is represented, according to A. Werner's scheme, by the formula $[Mg(OH_2)_6]Cl_2$, and similarly with the other salts crystallizing with six mols. of water. A. Werner thinks that the alums $KAl(SO_4)_2.12H_2O$, and other hydrates with an abnormally large proportion of water, owe their existence to the addition of polymerized mols. of water; $(H_2O)_2$, or H_4O_2, is then attached as one mol. to the central aluminium atom, and alum becomes $[Al(H_4O_2)_6](SO_4)_2K$. With these sulphates, A. Werner considers that one mol. of the water is attached to the sulphate residue: $Zn(H_2SO_4)6H_2O$, or $[Zn(H_2O)_6]H_2SO_4$, in agreement with the great difficulty involved in driving off the last mol. of water, and with the fact that both potassium and ammonium sulphates are anhydrous, and when introduced into a sulphate with seven mols. of water, the resulting double salt crystallizes with six. The water of crystallization is thus a source of difficulty with the co-ordination theory. Hence, in studying the hydrates, it is necessary to distinguish between acidic and basic water. Many of the hydrates have not yet been studied in the light of A. Werner's hypothesis. The subject was discussed by H. T. F. Rhodes,[2] and J. M. Brown.

It may be added that A. Werner's theory furnishes an interesting explanation of the apparent isomorphism of such pairs of compounds as $K_2SnCl_4.2H_2O$

and $K_2FeCl_5.H_2O$; $MnCl_2.4H_2O$ and $BeNa_2F_4$, which can be respectively formulated:

$$[SnCl_4(H_2O)_2]K_2 \qquad [FeCl_5.H_2O]K_2 \qquad [Mn(H_2O)_4]Cl_2 \qquad [BeF_4]Na_2$$

This shows that these pairs of compounds have a similar constitution in spite of the apparent dissimilarity exhibited by the ordinary chemical formulæ. The general subject has been discussed by:

A. Werner, *Neuere Anschauungen auf dem Gebicte der anorganischen Chemie*, Braunschweig, 1913; London, 1911; B. Schwarz, *Chemie der anorganischen Komplexverbindungen*, Berlin, 1920; London, 1923; and J. D. M. Smith, *Chemistry and Atomic Structure*, London, 1924.

N. Bohr [3] discussed the fitness of configurations of the electrons in various atoms for the formation of ions. N. V. Sidgwick has extended Bohr's theory to the electronic structure of atoms in co-ordination compounds. The subject was also discussed by J. D. M. Smith, and others at the Faraday Society's discussion on *The Electronic Theory of Valency*. A. Job discussed the catalyzed reaction $NH_3+HCl=NH_4Cl$ on the assumption that an unstable electronic system is formed as an intermediate product.

§ 20. The Metal Ammines, or Metalammoniates

T. Weyl[1] showed that sodium and potassium, and G. Gore that sodium, are soluble in liquid ammonia; C. A. Seely observed that these elements, as well as lithium and rubidium, are soluble in that menstruum; and H. Moissan studied soln. of rubidium and cæsium in liquid ammonia. Conc. soln. are copper-red, and have a bronze lustre, but dil. soln. are blue. The blue colour of the soln. recalls the blue-coloured halide salts of potassium and sodium; and the blue-coloured soln. of the alkali metals in the fused amide observed by A. W. Titherley. The colour of the soln. differs but slightly for different metals, although the appearance of yellow tints is noticeable in the case of calcium. More dil. soln., beginning at about 2 or 3 times normal, show no metallic lustre, but possess a very characteristic deep blue colour. In thin films, the conc. soln. likewise appear blue in transmitted light; but even for the blue rays the absorption is very great. A soln. of sodium in ammonia containing 0·004 gram-atom of metal per litre, just allows the filament of a 16-candle-power lamp to be distinguished through a thickness of 1 cm. The absorptive power of potassium in ammonia is practically identical with that of sodium. W. Palmaer, and C. A. Kraus also obtained blue soln. by electrolyzing liquid ammonia soln. of tetraalkyl ammonium salts. The methyl, ethyl, and propyl salts give blue soln., but not the amyl salt. The blue colour is ascribed to the presence of the free electropositive group NR_4—*vide* ammonium amalgam, **4**. 31, 38. According to O. Ruff and E. Geisel, 100 mols of liquid ammonia dissolve 21·1 gram-atoms of potassium at 0°; 20·9, at —50°; and 20·7, at —100°. The solubility thus increases slightly with rise of temp. Similarly, 100 mols of liquid ammonia dissolves 16·3 gram-atoms of sodium at 22°; 17·03, at 0°; 18·1, at —30°; 18·55, at —50°; 19·23, at —70°; and 20·1, at —105°. The solubility thus decreases with rise of temp. With lithium, 100 mols. of liquid ammonia dissolve 25·4 gram-atoms of the metal at all temp. between 0° and —80°. Lithium was found by C. A. Kraus to be soluble in ethylamine, but less so in methylamine, and insoluble in propylamine. Potassium dissolves rather slowly in ethylenediamine. Sodium and potassium are insoluble in ethylamine, and, according to H. Moissan, insoluble in methylamine free from ammonia. C. A. Kraus also found lithium, sodium, and potassium to be insoluble in secondary and tertiary amines.

O. Ruff made soln. of potassium by the electrolysis of a soln. of potassium iodide in liquid ammonia, when the substance collects on the negative pole in copper-red drops. T. Weyl supposed that the blue soln. which he prepared contained veritable compounds analogous to ammonium, NH_4, but with a hydrogen atom replaced by one of the alkali metal. Hence the names **potassammonium,** NH_3K, and **sodammonium,** NH_3Na. C. A. Seely supposed the liquids to be simple soln. of the alkali metals in liquid ammonia. T. Weyl, and J. A. Joannis regarded them as soln. of compounds of the alkali metal and ammonia in the solvent ammonia. The evaporation of the soln. in air, said J. A. Joannis, furnishes a deep copper-red solid whose analysis corresponds with KNH_3; but O. Ruff and J. Zedner said that it is purely chance that the proportions J. A. Joannis found were 1 : 1. He gave for the heat of formation, $NH_{3gas}+K_{solid}=KNH_{3solid}+6{\cdot}3$Cals., or, $NH_{3liq.}+K_{solid}=KNH_3+1{\cdot}9$ Cals.; and $NH_{3gas}+Na_{solid}=NaNH_{3solid}+5{\cdot}2$ Cals., or, $NH_{3liq.}+Na_{solid}=NaNH_3+0{\cdot}8$ Cal. H. Moissan said that the temp. of dissociation of potassammonium at ordinary press., is —2°. C. A. Kraus and W. W. Lucasse found that the composition of the liquid phase of sodium in the presence of liquid ammonia is :

	−51·6°	−42·5°	−46·4°	−47·4°	−51·9°	−55·9°	−59·7°
Molar per cent. Na	7·09	4·97	2·64	6·27	2·09	1·81	1·62

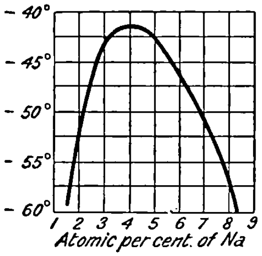

FIG. 44.—Solubility of Sodium in Liquid Ammonia.

The results are plotted in Fig. 44. H. P. Cady found the electrical conductivity is not electrolytic, but the conc. soln. behaves like a metal conductor, whose conductivity increases the greater the proportion of alkali metal in soln. Observations were made by E. Legrand; and M. Ascoli found that ammonia moves against the current through a plug of alumina, but if sodium be present, the direction is reversed. C. A. Kraus said that the conduction in liquid ammonia is ionic. The metal constitutes the positive ion and is identical with the positive ion of a salt of the metal dissolved in ammonia. The negative ion constitutes a new species of anion. It is supposed to consist of a negative charge, an electron, surrounded by an envelope of solvent mols. The electron is thus in equilibrium with ammonia according to the equation $\ominus(NH_3)_n\rightleftharpoons\ominus+nNH_3$; and at the same time, the electron is in equilibrium with metal cations and neutral metal atoms: $M^{\cdot}+\ominus\rightleftharpoons M$. J. A. Joannis said that the mol. wt. by vap. press. and f.p. methods correspond with the doubled formulæ, $NaH_3N.NH_3Na$, and $KH_3N.NH_3.K$. G. E. Gibson and T. E. Phipps measured the conductivity of soln. of the alkali metals in liquid ammonia and in methylamine. E. C. Franklin and C. A. Kraus determined the mol. wt. of sodium and lithium in liquid ammonia by the b.p. method; and C. A. Kraus, by the vap. press. method. The changes of press. with soln. more conc. than $0{\cdot}1N$, are smaller than those represented by the usual vap. press. law; this is due to the tendency of the soln. to separate into two phases for which the critical point is 3 molar per cent. of metal. O. Ruff and J. Zedner found the b.p. curves of liquid ammonia soln. of lithium, sodium, potassium are of the usual type at small conc., but with more than 8 at. per cent. of the metal, the curves begin to rise rapidly, indicating the possible existence of true compounds. With sodium, above —46°, one liquid phase exists at any conc., but below this temp. two liquid phases or one solid and one liquid phase are present. There is a eutectic at —111° on the f.p. curve corresponding with Na : $5NH_3$. C. A. Kraus and co-workers measured the sp. gr. of the soln. O. Ruff and J. Zedner gave for the b.p. of soln. in liquid ammonia :

	Li			Na			K		
At. per cent.	2·31	5·74	11·83	0·91	5·23	11·16	0·73	2·36	5·54
B.p.	−33·1°	−32·7°	−29·5°	−33·33°	−33·1°	−30·5°	−33·2°	−33·0°	−32·5°
Mol. wt.	10·9	12·3	4·9	36·2	75·4	20·1	74·8	64·0	67·9

for the f.p. of these soln. :

	Li			Na			K		
At. per cent.	6·8	9·9	15·6	2·3	8·3	15·9	2·0	5·9	12·0
F.p. I.	−77°	−77·5°	--79°	−77°	−78°	−81°	−76°	−78°	−83°
F.p. II.	—	—	—	−115°	−109°	−111°	—	—	—

and for the temp. of complete miscibility of the two phases with sodammonium :

At per cent. Na	0·5	0·8	1·4	2·8	5·9	8·3	12·9
Temp.	miscible		−50°	−47°	−54°	−61°	−72°

C. A. Kraus and W. W. Lucasse measured the electrical resistance of soln. of potassium and sodium in liquid ammonia.

The blue soln. of the alkali metals in ammonia gradually decompose into the metal amide and hydrogen : $2NaNH_3=2NaNH_2+H_2$. C. A. Kraus found that the stabilities of the soln. increase approximately in the order : potassium, calcium, lithium, and sodium. O. Ruff and E. Geisel found that at room temp. the soln. of potassammonium decomposes in two or three days $KNH_3=KNH_2+H$; and at higher temp., the decomposition is faster ; and at −60° in the presence of platinized asbestos, the soln. is decomposed in a few hours. The decomposition of rubidammonium occurs in 6–10 hrs. at ordinary temp. ; cæsammonium, in 1–2 hrs. ; lithammonium, and sodammonium, in 2–3 weeks. There is no evidence of the formation of a definite compound on the vap. press. curves, Fig. 45. J. A. Joannis, and E. C. Franklin found that the reaction, however, is catalyzed by metal oxides, hydroxides, etc. The temp. at which the alkali metals are attacked by ammonia vapour at atm. press. were found by H. Moissan to be lithium, 70° ; sodium, −20° ; potassium, −2° ; rubidium, −3° ; cæsium, 40° ; and calcium, 20°. Solid ammonia at −80° has no action on these metals. The decomposition of the soln. is more rapid in light than in darkness, and J. A. Joannis found that the rate at which hydrogen is evolved in a sealed tube decreases with time. He attributed this to the influence of the increasing hydrogen press. on the rate of the reaction, but C. A. Kraus found no evidence of a decrease in the rate of the reaction by increasing the conc. of the hydrogen. There is a steady increase in the velocity of the reaction up to a constant rate. The acceleration is attributed to the catalytic influence of sodamide. The rate of evolution of hydrogen finally slackens as the reacting constituents are consumed. According to J. A. Joannis, if a slow current of *oxygen* be passed through the soln., the liquid becomes bluish-black, then blue, and finally colourless. A gelatinous precipitate is formed whose composition approximates **sodium amminomonoxide,** $Na_2O.NH_3$. This substance dissolves in water with the evolution of much heat, but no gas is formed. T. Weyl likewise obtained **potassium diamminomonoxide,** $K_2O.2NH_3$; with a more protracted contact, the higher alkali oxides are formed. According to H. Schrader, the amides of the alkali metals undergo autoxidation, with the formation of nitrite, hydroxide, and ammonia. When finely-divided sodamide is exposed to air in presence of a little water, a yellowish-red oxidation product is formed, which is a peroxide, probably of the formula $NaNH_2O_2$. A sample of sodamide gave in fifty-eight days at ordinary temp. 0·44 mol. per cent. peroxide and 6·9 per cent. nitrite. In dry air, autoxidation does not take place at the ordinary temp., but at 100° to 110° the peroxide is slowly formed. The peroxide is stable in dry air, but in moist air is changed into a white substance, the aq. soln. of which gives the peroxide reaction. C. Hugot found that *sulphur* forms a sulphide ; *selenium,* a selenide ; and *tellurium,* a telluride. J. A. Joannis said that *nitrogen* has no action ; *nitrous oxide* reacts : $N_2O+2KNH_3=KNH_2+NH_3+KOH+N_2$; and with a longer action : $N_2O+2KNH_3=KN_3+KOH+2NH_3$; and *nitric oxide* forms the alkali hyponitrite, KNO. C. Hugot found that with *phosphorus* and sodammonium, $PNa_3.PH_3$,

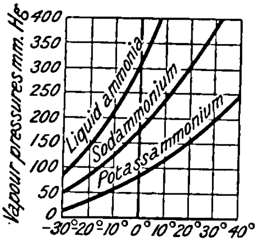

FIG. 45.—Vapour Pressure Curves.

is formed; with *arsenic*, $AsNa_3.AsH_3$; and with *phosphine*, J. A. Joannis obtained $PH_2.Na$. Sodammonium is attacked by *antimony*. H. Moissan obtained with dry *carbon monoxide*, potassium carbonyl, KCO; E. Rengade obtained with *carbon dioxide* at $-50°$, sodium carbonate and hydrogen, and at $-25°$ to $-35°$, some formate is also produced. H. Moissan obtained with *acetylene*, $C_2Na_2.C_2H_2$, or C_2Na_2, according to the conditions—*vide* carbides. Potassammonium yields $C_2K_2.C_2H_2$. J. A. Joannis found that sodammonium forms with *lead*, a lead-sodium ammonia compound: potassammonium attacks *mercury;* and *sodium chloride* forms a complex sodium chloroamide. C. A. Kraus and H. F. Kurtz found that when metallic salt is added to a soln. of a more electropositive metal in ammonia, precipitation of the metal (from the salt), either alone or as a compound with the other, may occur. The theory of the various possible cases is fully discussed. Salts of mercury, cadmium, zinc, tin, lead, antimony, bismuth, and thallium reduced thus by sodium all give compounds with sodium, but silver is precipitated alone. Some of the intermediate compounds of sodium with mercury, tin, and lead are not stable in contact with the soln., but decompose to compounds poorer in sodium. Mercuric ethyl chloride, by the same treatment (with excess of sodium), gives the compound NaHg, identical with that obtained by reducing ordinary mercury salts. In addition, the compounds NaCd, $NaZn_4$, Na_4Sn, Na_4Pb, and Na_3Tl_2 were formed. In the case of calcium, in place of sodium, CaAg, Ca_7Zn, Ca_3Hg_2, Ca_2Pb_3, and Ca_5Sn were thought to be formed.

H. Moissan reported that **lithammonium,** $LiNH_3$, is obtained as a brownish-red solid when the liquid produced by the action of dry ammonia gas on lithium at ordinary temp. is rapidly heated to 70°; if produced at lower temp., it always contains more ammonia than that demanded by the above formula. When allowed to remain for any length of time at the ordinary temp., a soln. of lithium ammonia in liquid ammonia yields lustrous, transparent crystals of lithamide. This reaction proceeds more rapidly at 65°–80°, and appears to be independent of the press. If solid lithammonium heated at 50° or 60° is exposed to the rapid action of the vacuum pump, ammonia is evolved and crystalline lithium is obtained; if the exhaustion is effected more slowly at ordinary temp. hydrogen is also evolved, and the residue consists of lithium and lithamide. Lithammonium is oxidized when exposed to air. With ammonium chloride, hydrogen, ammonia, and lithium chloride are formed. Acetylene forms $C_2Li_2.C_2H_2.2NH_3$. If the blue soln. of lithammonium is allowed to stand 24 hrs. at ordinary temp. there is formed a brownish-red substance which has the composition $Li(NH_3)_3$. H. Moissan obtained with methylamine and lithium, $LiNH_3.NH_2$. C. A. Kraus measured the vap. press. of a sat. soln. of lithium in liquid ammonia, *i.e.* of $LiNH_3$, prepared by H. Moissan, and found 9·98 cms. at 20·3°; 9·53 cms. at 19·3°; 5·70 cms. at 9·75°; and 3·31 cms. at 0°. From the relation $Q=4{\cdot}6T_1T_2/(T_2-T_1)(\log p_2/p_1)$, he obtained 8698 cals., which represents the heat evolved when a mol of ammonia vapour combines with the metal under equilibrium conditions to form a sat. soln. By studying the vap. press. curves, F. Benoit observed that soln. of lithium in liquid ammonia contain $Li.4NH_3$, which easily decomposes into lithamide, hydrogen, and ammonia. There is no evidence of $Li.NH_3$. The mol. wt. corresponds with $Li_2.8NH_3$, and its heat of formation: $2Li_{solid}+8NH_{3gas}=Li_2.8NH_{3liq.}+8{\cdot}67$ Cals. C. A. Kraus and W. C. Johnson were unable to verify this for liquid ammonia at $-39{\cdot}4°$ containing between 3·61 to 60 mols of ammonia per gram-atom of lithium. The curve is continuous, rising rapidly with increasing dilution, and then more slowly until the region of two liquid phases is reached, when the press. remains constant at 540 mm. —that of ammonia alone is 555 mm. There is no evidence of the formation of compounds of the alkali metals with ammonia of the ammonium type.

H. Moissan found that **cæsammonium,** $CsNH_3$, is formed when ammonia under atm. press. acts on cæsium in the form of fine wire at 40°. On cooling by means of a mixture of acetone and solid carbon dioxide, a blue liquid is obtained from which the crystalline, brass-coloured, cæsammonium separates. When brought into contact with the air, it takes fire. It dissolves in liquid ammonia to form a blue, oily soln.; if this soln. be warmed or placed under reduced press., dissociation takes place and small crystals of cæsium are obtained. Rubidium is not attacked by liquid ammonia at —75°, but at a slightly higher temp. action takes place, and a blue soln. containing **rubidammonium**, $RbNH_3$, is formed. Rubidium is first attacked by gaseous ammonia at atm. press. at —3°. The metal-ammonium easily dissociates and leaves small, prismatic crystals of rubidium. The reactions with acetylene resemble those with the other alkali metals.

While T. Weyl, J. A. Joannis, and H. Moissan consider that the soln. of the alkali metals in liquid ammonia contain compounds of ammonia and the metal, C. A. Seely, C. A. Kraus, and O. Ruff and E. Geisel say that the soln. are soln. of the metal in ammonia or mixtures of the metal with a soln. of the metal in liquid ammonia. If the copper-coloured substances be squeezed between folds of cloth in a filter-press, O. Ruff and E. Geiscl separated solid metal, and a sat. soln. of the metal in liquid ammonia. Following C. A. Kraus, let *FE*, Fig. 46, represent the composition of soln. of sodium in ammonia in equilibrium with solid ammonia. Soln. with a conc. between *d* and *e* are in equilibrium with soln. of conc. between *d* and *e* along the curve *EDC* so that two liquid phases are present. Solutions represented by points on the curve *CB* soln. have a concentration between *b* and *c*, and are in equilibrium with solid ammonia, while solutions represented by points on *BA* are in equilibrium with solid sodium, consequently, *AB* is the solubility curve of sodium in ammonia. On cooling, the soln. whose composition lies between *e* and *c*, separates into two liquid phases; the two soln. are mutually soluble in all proportions at the point *D* which has not been located exactly—probably it is not far from —50°. A solution of the metal in ammonia will form a two-component system (NH_3 and metal) with two phases (soln. and vapour) so that if ammonia be gradually withdrawn from the system, the press. will vary with the conc. of the soln. (bivariant system), and become constant only when a third phase appears (univariant system). If the third phase subsequently disappears, the press. will again vary (bivariant system) as ammonia is withdrawn. If the third phase changes abruptly, producing a new (third) phase, the vapour press. will change to a new constant value. The system under consideration does not change in this way when the supposed metal-ammonia compounds separate from the soln., for if ammonia gas be gradually withdrawn from a vessel containing a very dil. soln. of, say, sodium in ammonia, the vapour press. decreases with increasing conc. until the soln. separates into two layers, a dark blue, more dil. soln. below, and a bronze-coloured, more conc. soln. above. The vapour press. remains constant until all the dil. soln. has disappeared. The vapour press. again decreases with increasing conc. until the soln. is sat. and a solid begins to separate, when the press. remains constant until nothing but ammonia and free metal remain. It might therefore be expected that the solid which first separates is also free metal, but J. A. Joannis says that it is not so because the solid which initially separates has the same colour as the soln., and it also has a metallic reflection, while the free metal has a silver-white metallic reflection; J. A. Joannis also assumes that the dissociation press. of the alleged compound is exactly equal to the vapour press. of the sat. soln. in order to explain the passage from compound to metal without an appreciable change of press. However, the fact discovered by J. A. Joannis that at a series of different temp. there is no change of press. from the moment the solid phase begins to separate until nothing but free metal and gaseous ammonia remain, is not in harmony with the phase rule if a compound is initially formed which dissociates subsequently: $NaNH_3 \rightleftharpoons Na + NH_3$, for

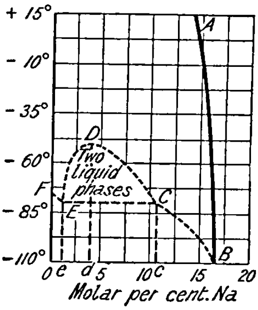

FIG. 46.—Solubility of Sodium in Liquid Ammonia.

the solid phase must consist of nothing more than free metal and a sat. soln. of the metal in ammonia. The system will be invariant—two components and four phases—and such a system can exist only at one definite fixed temp., yet experiment shows that such a system does not exist. Hence, a fourth solid phase cannot be present if the phase rule is valid. There is therefore no satisfactory evidence of the chemical individuality of ammines of the alkali metals.

According to H. Moissan, if ammonia be passed over crystalline calcium, there is a rise of temp.; and if the temp. be kept at 15°–20°, the calcium becomes brownish-red, and swells up, but does not form a soln. as do the alkali metals. Liquid ammonia dissolves a little, forming a blue soln. The product inflames when exposed to air; and at —80°, ammonium chloride gives ammonia and hydrogen. H. Moissan said that the product is *calcium tetrammine*, $Ca(NH_3)_4$. C. A. Kraus, however, showed that this product must have been a mixture because the compound actually formed is **calcium hexammine,** $Ca(NH_3)_6$. He found that if ammonia be gradually withdrawn from a sat. soln. of calcium in ammonia at —33°, the vap. press. gradually falls as represented by the curve *AB*, Fig. 47; at *B*, the soln. separates into two layers, a dil. and a conc. soln., and the vapour press. remains constant, *BC*, until the dil. soln. disappears at *C*. Afterwards, the press. gradually falls from *C* to *D* as ammonia is withdrawn, until, at a press. of 471·8 mm. (—32·5°) a solid compound appears, and this press. remains constant, *DE*, until the sat. soln. disappears, when the press. falls abruptly from *E* to *F*—about 1·8 mm., and the metal calcium appears. This press., *EF*, remains constant so long as the solid compound remains undecomposed. Analysis agreed with the hexammine formula. The solid compound does not lose its ammonia in steps, thus showing that only one compound is formed which dissociates directly into the metal and ammonia: $Ca(NH_3)_6 \rightleftharpoons Ca + 6NH_3$. There is no sign of H. Moissan's $Ca(NH_3)_4$ on the vap. press. curve. W. Biltz and G. F. Hüttig gave 10·32 Cals. for the heat of formation of calcium hexammine. The old names of these compounds and their supposed constitution as compounds of the alkali metals with ammonia are based on the hypothesis that the compounds $NaNH_3$ and KNH_3 have an ammonium structure; but since these substances do not exist, and since the known compounds of the metals of the alkaline earths are formed by the union of the metal with six mols. of ammonia per atom of metal, O. Ruff and co-workers say that the ammonium theory must be abandoned, and with it, the term metal-ammonium. The term, however, is good enough when meaning a soln. of the alkali metal in liquid ammonia. The pasty condition of the calcium-ammonium compound is attributed by E. Botolfsen to the presence of traces of sodium, and he believed that calcium can form a number of ammines with ammonia. When the calcium ammine is heated in vacuo, at about 34°, it decomposes explosively, forming calcium nitride and hydride, and hydrogen gas. According to G. Roederer, when dry liquid ammonia acts on strontium at —60°, reddish-brown crystals of **strontium hexammine,** $Sr(NH_3)_6$, are formed, and they dissolve in liquid ammonia to give a deep blue soln. The dissociation press. of the crystals is about 10 mm. at —40°, and 760 mm. at 46°. When strontium hexammine is exposed under reduced press., it decomposes slowly at 20°, and very rapidly above this temp., evolving a mixture of ammonia and hydrogen and leaving a white mass of strontiamide, $Sr(NH_2)_2$. W. Biltz and G. F. Hüttig gave 9·91 Cals. for the heat of formation of strontium hexammine. G. Roederer added that when a soln. of strontium hexamine is treated with carbon monoxide at —45°, a dull yellow, pulverulent mass of strontium carbonyl, $Sr(CO)_2$, is obtained; this becomes bright yellow on exposure to moist air, forms a limpid, yellow soln. with water, and blackens when

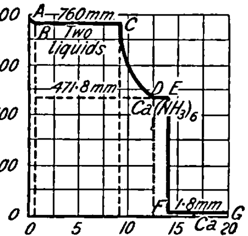

FIG. 47.—The Solubility of Calcium in Liquid Ammonia.

heated under reduced press., yielding a mixture of strontia, strontium carbonate, and carbon. By the action of oxygen on strontium hexammine, dissolved in ammonia soln., cooled to —55°, the deep bluish-black colour lightens and finally disappears, and, on allowing the ammonia to evaporate, a mixture of strontia and strontium dioxide is obtained. Nitrogen dioxide also reacts with strontium hexammine, dissolved in ammonia soln., forming strontium hyponitrite. According to A. Guntz, when barium is treated with gaseous or liquid ammonia, a compound is formed, which R. C. Mentrel showed to be **barium hexammine**, $Ba(NH_3)_6$. The compound is made by passing ammonia over cold barium, when a red solid first appears which, at —23°, passes into a blue liquid, and, at —50°, into a blue oil which is sparingly soluble in liquid ammonia. The compound is stable below —15°, but above this temp., it is converted into an amide. Barium hexammine inflames spontaneously in air, and is violently decomposed by water; it absorbs oxygen, forming a mixture of barium monoxide and dioxide; and with nitric oxide it forms barium hyponitrite. W. Biltz and G. F. Hüttig gave 9·65 Cals. for the heat of formation of barium hexammine. According to A. Guntz and R. C. Mentrel, when barium hexammine, dissolved in liquid ammonia, is treated at —50° with dry oxygen, the latter is absorbed with the formation of a white, gelatinous precipitate of indefinite composition, which, when dissolved in hydrochloric acid, is decomposed with the formation of ammonia and hydrogen dioxide. Carbon monoxide, under the same conditions, produces barium carbonyl, $Ba(CO)_2$, a yellow powder, which is unstable in air, becomes brown at 100°, and incandescent at 250°, forming barium oxide and carbonate and carbon.

According to C. A. Seely, magnesium is insoluble in liquid ammonia, but C. A. Kraus reported that it dissolves in liquid ammonia if precautions be taken to have a clean metal surface in contact with the solvent; and A. G. Loomis obtained an amalgam of **magnesium hexammine**, $Mg(NH_3)_6.Hg_n$, in his study of the system: mercury-magnesium and liquid ammonia. C. A. Seely also said that aluminium, thallium, indium, mercury, and copper are not dissolved by liquid ammonia—*vide supra*, solvent action of liquid ammonia. T. Weyl showed that although liquid ammonia does not act on zinc, yet, when sodammonium is treated with zinc diamminoxide, a *zinc ammine* is formed: $2NaNH_3+ZnO.2NH_3=(NH_3Na)_2O+Zn(NH_3)_2$. The deep blue liquid has a metallic lustre, and decomposes in the course of a day at a temp. of 12°–16°. T. Weyl also prepared a *mercury ammine* by the action of sodammonium on mercuric chloride.

Ammonia gas was found by F. Jones [2] to be absorbed by dry sulphur, and if heat be applied, ammonium sulphide and nitrogen are formed. J. B. Senderens said that these products are formed by the action of aq. ammonia on pure sulphur at ordinary temp., but, according to C. Brunner, sulphur is insoluble in aq. ammonia. If the two be heated for some days in a sealed tube, F. A. Flückiger found that ammonium polysulphide and thiosulphate are formed; and W. P. Bloxam found that heating under press. is necessary for the reaction. According to H. Moissan, liquid ammonia acts at —38° on γ-sulphur; at 15·5°, on β-sulphur; and at —11·5°, on α-sulphur. In a sealed tube, at 20°, liquid ammonia dissolves about 30 per cent. of sulphur, forming a purple-red soln. of what he called **sulphammonium,** $S(NH_3)n$, he regarded this as a definite compound—between 0° and 20°, the composition corresponded with $S(NH_3)_4$, or $(NH_3)_2S.2NH_3$; at —23°, the formula corresponded with $(NH_3)_3S$, or $(NH_3)_2S.NH_3$, so that no definite formula can be given for the alleged compound. G. Gore, C. A. Seely, E. C. Franklin and C. A. Kraus, and C. Hugot considered the reddish-purple liquid to be a simple soln. of sulphur in liquid ammonia. H. Moissan obtained sulphammonium as a purple-red soln. by the action of liquid ammonia on sulphur in a sealed tube. If the soln. be cooled 4°–5° below the f.p. of liquid ammonia, it becomes solid without the separation of sulphur. If the dil. soln. be heated to 90°, the intensity of the colour diminishes, and at 131°, the critical temp. of ammonia, the liquid becomes colourless, and crystals of sulphur separate out. The liquid when cooled to 100°

again becomes colourless, and the original purple-red colour is restored at ordinary temp. If sulphammonium be a simple soln., said H. Moissan, it is not clear how at 100° the solid and solvent can exist beside one another. O. Ruff and E. Geisel thought that the soln. might contain hydrogen sulphide, nitrogen sulphide, and *thiodiimide*, $(NH)_2S$, or *dithiodiimide*, $(NH)_2S_2$. They represent the first stage in the formation of sulphammonium as a reversible reaction: $10S+4NH_3 \rightleftharpoons 6H_2S+N_4S_4$, the two products on the right may form compounds with ammonia. The hydrogen sulphide can be precipitated with silver iodide, and nitrogen sulphide obtained from the residue. The same final state can be obtained by the action of hydrogen sulphide on a soln. of nitrogen sulphide in liquid ammonia. The blue sulphamide soln. can also be obtained by the action of liquid ammonia and hydrogen sulphide on lead dithiodiimide, $PbN_2S_2+3H_2S=PbS+2NH_3+4S$; and on mercury thiodiimide, $HgN_2S+3H_2S=HgS+2NH_3+3S$. The soln. is decolorized by the addition of ammonium sulphide which presumably forms a polysulphide, while a small proportion of ammonium sulphide added to a liquid ammonia soln. of nitrogen sulphide produces a blue soln. O. Ruff and E. Geisel say that all these facts, and possibly also the dichroism of the sulphammonium soln.—red in transmitted, blue in reflected light—are in harmony with the assumption that the intense purple-coloured substance is partly a colloidal sol. of elemental sulphur in liquid ammonia, and partly a mixture of the products of a reaction between sulphur and ammonia. This hypothesis is not contradicted by any of H. Moissan's observations. P. Lebeau and P. Damoiseau claim that if the materials be all thoroughly dried, the reactions described by O. Ruff and E. Geisel do not occur. F. W. Bergstrom showed that the action of soln. of sulphur in liquid ammonia on the metal cyanides indicates that the equilibrium: $10S+4NH_3 \rightleftharpoons 6H_2S+N_4S_4$ probably does occur, but there are quite a number of other reactions involved: *e.g.* $10S+4NH_3 \rightleftharpoons S_4N_4+6H_2S$; $H_2S+2NH_3=(NH_4)_2S$; $S_4N_4+2NH_3=2S(NH)_2+S_2(NH)_2$; $(NH_4)_2S+nS=(NH_4)_2S_{n+1}$; $(NH_4)_2S_{n+1} \rightleftharpoons (NH_4)_2S_n+S$; etc.

According to O. Ruff and L. Hecht, the f.p. curve, Fig. 48, of mixtures of sulphur and ammonia falls from −77·34° to a eutectic at about −79·7° and 16·3 per cent. of sulphur; it then rises to a maximum at −78·3° and 24 per cent. of sulphur corresponding with **sulphur hexammine,** $S(NH_3)_6$; the curve then falls to −84·6° at a composition corresponding with **sulphur triammine,** $S(NH_3)_3$. The existence of this compound is shown by the break in the solubility curve, Fig. 48. Both compounds are probably associated to form doubled molecules in soln. H. Moissan's *sulphur diamine*, $S(NH_3)_2$, is not present in the system. It was therefore inferred that the assumed equilibrium $10S+4NH_3 \rightleftharpoons 6H_2S+N_4S_4$ is of minor importance as most of the sulphur is present in the form of ammines. O. Ruff and L. Hecht also examined the absorption of light by the soln., and the results indicate the probable existence of several compounds in the soln. A. K. Macbeth and H. Graham obtained **sulphur hexitamide,** or **hexasulphamide,** $S_6(NH_2)$, by adding alcohol to mixed chloroform soln. of ammonia and sulphur monochloride to precipitate the nitrogen tetrasulphide, and evaporating the mother-liquor. The colourless, square plates melt at 105°; they are insoluble in water, but soluble in organic solvents. This compound gives a coloration with alcoholic soln. of potassium hydroxide, or of organic bases. The coloration may be due to a salt of a nitrogen-sulphur acid.

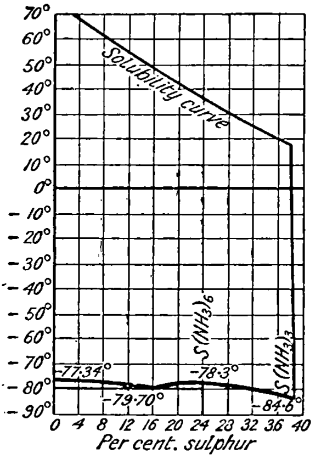

FIG. 48.—Equilibrium Diagram of the System: Sulphur-Ammonia.

H. Moissan found that when a mixture of nitrogen, ammonia, and sulphur is exposed to 45 atm. press. at —12°, or 20 atm. at —40°, ruby-red crystals of sulphammonium are formed. These dissolve in an excess of liquid ammonia. The red colour can be detected when but 0·00061 per cent. of sulphur is present; a trace of water imparts a greenish colour to the soln. The liquid freezes at —85° to a red mass without the separation of sulphur. If the soln. is not sat., white plates of solid ammonia melting at —75° can be detected when the solid is melting. The vap. press. curve of sulphammonium is nearly parallel to that of liquid ammonia. The liquid shows a characteristic absorption spectrum—with dil. soln., there is an absorption band cutting off the yellow and orange parts of the spectrum, and another cutting off the blue with portions of the green and violet; with conc. soln., all except a green band and the least refrangible portion of the red end of the spectrum is cut off. Sulphammonium is soluble in absolute alcohol, dried ether, and many other solvents. These soln. are stable at low temp. If ether cooled to —80° be added to a soln. of sulphammonium, a homogeneous purple-red liquid is formed, but if more ether is added, the soln. becomes blue; at —40°, the blue soln. is decolorized with the separation of sulphur. The soln. prepared with chloroform at —80° is purple-red, but at 15°, it suddenly becomes yellow with the separation of crystalline sulphur. Some liquids which do not mix with the sulphammonium may react with it—benzene, for instance, gives a brown soln., carbon disulphide, a blue one; carbon tetrachloride, colourless crystals and an orange-yellow compound which dissociates at ordinary temp.

According to O. Ruff and E. Geisel, if sulphammonium be slowly evaporated in air, a pale red mixture of sulphur with a number of other substances is formed. After standing for a long time, the mixture gradually loses its colour, and sulphur alone remains. If a quick current of hydrogen be passed through the evaporating liquid, the liquid ammonia first volatilizes, then follows ammonium sulphide, and nitrogen sulphides remain. The gases which pass off contain some hydrogen sulphide. H. Moissan said the sulphammonium can transform many substances into sulphides. Brown ammoniacal soln. of iodine are decolorized by an excess of sulphammonium with the evolution of ammonia. Molten selenium has no action; a soln. of calcium in ammonia forms white calcium sulphide; if the sulphammonium be in excess, red crystals are formed. At ordinary temp., sulphammonium reacts with mercury, forming crystals which dissociate and produce mercury sulphide; dried calcium oxide forms red crystals and a solid which easily dissociates; zinc oxide forms orange-yellow crystals; sodium chloride and bromide are not attacked; anhydrous magnesium chloride forms a yellow crystalline compound; lead chloride forms yellow crystals which dissociate in air under atm. press.; mercuric chloride produces a dark-coloured substance insoluble in liquid ammonia, but which dissociates in air to mercuric sulphide.

§ 21. The Substituted Ammonias—The Amines, Amides, and Imides

> The eye may rest with complacency upon the simple beauty of the law which governs the construction of bodies belonging to the type of ammonia.—A. W. HOFMANN.

The hydrogen atoms of ammonia can be replaced, one by one, by equivalent radicles—methyl, CH_3 ; ethyl, C_2H_5 ; . . . to form a series of compounds called the **amines** or **substituted ammonias** in which nitrogen is undoubtedly tervalent. The amines are distinguished as primary, secondary, or tertiary, according as one, two, or three of the hydrogen atoms in ammonia are replaced by these radicles. Thus:

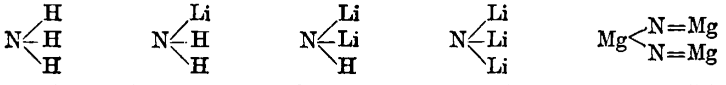
$$\genfrac{}{}{0pt}{}{H}{H}{>}H{-}N \qquad \genfrac{}{}{0pt}{}{CH_3}{H}{>}N{-}H \qquad \genfrac{}{}{0pt}{}{CH_3}{CH_3}{>}N{-}H \qquad \genfrac{}{}{0pt}{}{CH_3}{CH_3}{>}N{-}CH_3 \qquad \genfrac{}{}{0pt}{}{CH_3}{CH_3}{>}N{-}C_2H_5$$

Ammonia. Methylamine. Primary. Dimethylamine. Secondary. Trimethylamine. Tertiary. Dimethylethylamine. Tertiary.

The existence of the alkylamines was predicted by J. von Liebig,[1] 1837 ; in 1849, A. Wurtz obtained the primary alkylamines; and in 1851, A. W. Hofmann prepared the primary, secondary, and tertiary alkylamines, and also the alkylammonium bases or the quarternary ammonium bases in which all four atoms of the ammonium group are replaced by the alkyl radicles. The basic character of ammonia is retained by the amines, and since the alkyl radicles are themselves basic, the aliphatic amines are even more basic than ammonia itself. W. Ostwald made an estimate of the basicity of the ethyl ammonias, and found the relative strengths of these bases:

NH_3	$(C_2H_5)NH_2$	$(C_2H_5)_2NH$	$(C_2H_5)_3N$	$(C_2H_5)_4NOH$
4·8	20·5	28·3	20·2	128·0

The basic properties of the aromatic amines decrease with the number of radicles introduced ; the primary aromatic amines are stable ; the secondary aromatic amines are decomposed by water ; and the tertiary aromatic amines are unstable. In organic chemistry, compounds containing the monadic group NH_2 are called **amines** or **amides** ; and compounds with the dyadic group NH are called **imides**. The existence of compounds like



$$N\begin{cases}H\\H\\H\end{cases} \qquad N\begin{cases}Li\\H\\H\end{cases} \qquad N\begin{cases}Li\\Li\\H\end{cases} \qquad N\begin{cases}Li\\Li\\Li\end{cases} \qquad Mg{<}\genfrac{}{}{0pt}{}{N{=}Mg}{N{=}Mg}$$

Ammonia. Lithium amide. Lithium imide. Lithium nitride. Magnesium nitride.

in which one or more hydrogen atoms is replaced by a metal, is sometimes cited as evidence that ammonia is a weak tribasic acid.

In 1809, H. Davy,[2] and J. L. Gay Lussac and L. J. Thénard independently sought to determine the composition of ammonia by passing the gas over sodium heated in a glass retort to about 300°. The glass of the retort was considerably corroded, and in the case of sodium, an olive-green crystalline mass was obtained. H. Davy's investigation of the action of water, J. L. Gay Lussac and L. J. Thénard's study of the action of heat, and F. Beilstein and A. Geuther's work on the action of hydrochloric acid on the olive-green compound showed that it is an amide of the alkali metal—**sodium amide** or **sodamide,** NH_2Na. When made in glass vessels, the sodamide is contaminated with products derived from its reaction with glass. It is best made in a silver, iron, or nickel vessel, when the resulting product is white. A. W. Titherley used an iron vessel in which the sodium was heated to 300°–400° in a current of dry ammonia. A. Guntz and F. Benoit used a similar process. L. M. Dennis and A. W. Browne prepared it in the apparatus depicted in Fig. 49.

A sheet iron vessel, *A*, with riveted joints and a double bottom, has a grooved rim *B* into which fits a cover *C*. The cover has three tubular openings fitted with rubber stoppers—one *D* is an inlet for ammonia, another *E* is the outlet, and the third is for a thermometer *F*. The ammonia inlet-tube leads into a nickel dish *G* which contains clean dry sodium, and stands upon a little tripod to prevent direct contact with the hot bottom of the iron vessel *A*. When the lid *C* is in position, the annular space of the rim is packed with sand. The vessel *A* rests on a thick iron plate heated by a suitable burner. The ammonia is dried in a tower of soda-lime; and the sodium heated to 100° or 400°. Hydrogen mixed with the excess of ammonia escapes. The reaction is represented $2NH_3+2Na=2NH_2Na+H_2$.

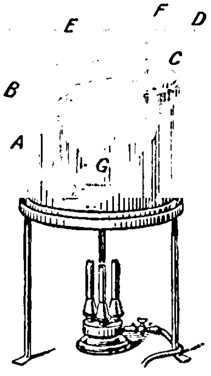

Fig. 49.—The Preparation of Sodamide.

L. Wöhler and F. Stang-Lund devised a special apparatus for the preparation of sodamide of a high degree of purity. F. Rössler passed the ammonia into fused sodium; once the reaction has started external heating is unnecessary. A. W. Titherley also made the amide by heating sodium oxide in a current of ammonia; J. A. Joannis, by keeping sodammonium for some time at ordinary temp.; and H. Moissan, by the action of ammonia on sodium hydride in the cold. T. Ewan made alkali amides by bringing a liquid ammonia soln. of the alkali metal and one of its salts—*e.g.* the cyanide—in contact with high carbon iron or steel as a catalyst; or by electrolyzing a soln. of an alkali salt—*e.g.* the cyanide—in anhydrous ammonia in the presence of high carbon steel or iron as catalyst, and with an alkali metal amalgam as cathode. The corresponding **potassium amide,** or **potassamide,** KNH_2, was made by H. Davy, and J. L. Gay Lussac and L. J. Thénard in a similar way to that they employed for sodamide. F. M. Baumert and H. H. Landolt, and A. W. Titherley made the amide in an analogous manner. The Badische Anilin- und Soda-fabrik made the alkali amides by passing ammonia gas into soln. of the alkali metals in fused anhydrous alkali hydroxide. The action takes place at about 275°. H. Moissan made **rubidium amide,** $RbNH_2$, by the action of ammonia on rubidium hydride, and by allowing rubidammonium to stand for some time. A. W. Titherley made it by the action of ammonia on rubidium at 200°–300°. H. Moissan also made **cæsium amide,** $CsNH_2$, in a similar way, and also found that a mixture of amide and nitride is formed when nitrogen is passed over heated cæsium hydride. E. Rengade made it by the action of dry ammonia on cæsium at 120°; and by the spontaneous decomposition of a soln. of cæsium in liquid ammonia. Clean lithium when exposed to ammonia in the cold acquires a bluish-white crust, but suffers no further change. A. W. Titherley made **lithium amide,** $LiNH_2$, by the action of ammonia on lithium at 400°, and H. Moissan, by heating a soln. of lithium in liquid ammonia to 65°–80°; and O. Ruff and H. Goerges also obtained it by the interaction of lithium and liquid ammonia in a sealed tube at ordinary temp. for two weeks. F. W. Dafert and R. Miklauz observed that in the action of nitrogen on lithium hydride, of hydrogen on lithium nitride, or of mixtures of nitrogen and hydrogen or ammonia on lithium hydride or nitride, lithium imide, lithium amide, or trilithium amide, or mixtures of these three substances are formed, the final product depending on the temp. and other experimental conditions. The amide can be readily obtained by the action of ammonia on amorphous lithium nitride at temp. between 130° and 350°, or on crystalline lithium nitride from 410° to 430°, or on lithium hydride from 440° to 460°, the changes taking place according to $Li_3N+2NH_3=3LiNH_2$ and $LiH+NH_3=LiNH_2+H_2$.

Lithium amide was stated by A. W. Titherley to furnish long, colourless, transparent needles or a white crystalline mass, which, when melted, appears pale green. O. Ruff and H. Georges described it as forming white, lustrous crystals, consisting of regular hexahedra mixed with octahedra and tetrakishexahedra, and of sp.gr. 1·178 at 18·5°. F. Beilstein and A. Geuther said that sodium amide furnishes crystalline masses which appear brown when cooling but olive-green or flesh-red when cold. The colour, said A. W. Titherley, is due to the presence of impurities, for sodamide can be readily obtained in white crystalline masses with a conchoidal fracture. J. L. Gay Lussac and L. J. Thénard's preparation of potassium amide was greenish-brown; F. M. Baumert and H. H. Landolt's was yellowish-brown or flesh-red, and in thin layers white; and A. W. Titherley's, a white mass with a waxy appearance. Rubidium amide was obtained by A. W. Titherley as a white, crystalline mass; and cæsium amide, by E. Rengade, in microscopic prisms or plates. O. Ruff and H. Georges said that lithium amide has a m.p. of 573°–575°, and it may be sublimed in ammonia. According to A. W. Titherley, lithium amide melts at 380°–400°; sodium amide softens at 149°, melts at 155°, and sublimes at 400°; potassium amide melts at 270°–272°; rubidium amide, at 285°–287°; according to C. A. Kraus and E. J. Cuy, sodium amide melts at 206·4°; and potassium amide, at 329·0°; J. M. McGee gave 208° for the m.p. of sodamide; and L. Wöhler and F. Stang-Lund, 210° for sodamide, and 338° for potassamide. No other breaks occurred in the cooling curves. According to E. Rengade, cæsium amide melts at about 260°. R. C. Mentrel said that when lithium amide is heated to 430° in a stream of ammonia, it begins to decompose giving off hydrogen and nitrogen and acquiring a yellow colour, but the amide is re-formed if the product is cooled in ammonia gas. In vacuo, decomposition begins at 370°; after heating to 450°, there remains white lithium imide, Li_2NH, or a mixture of imide and nitride. Decomposition is completed at 750°–800°. C. A. Kraus and E. J. Cuy's results for the m.p. of mixtures of sodium and potassium amides are summarized in Fig. 50. There is a eutectic at 92° with 33 molar per cent. of potassium amide, and a break in the curve at about 120° corresponding with the existence of an unstable sodium potassium triamide, $NaNH_2.2KNH_2$, which is largely dissociated in the molten mixture. When sodium amide is melted, it furnishes a pale green liquid which becomes dark green at 500°, and then appears to boil owing to its decomposition. In vacuo, decomposition begins at 330°, and is complete at 440°. The product obtained at 390° is a mixture of sodium, sodium nitride, and sodium amide. J. L. Gay Lussac and L. J. Thénard said that decomposition proceeds $3NaNH_2=Na_3N+2NH_3$, but A. W. Titherley found that sodamide begins to decompose into its elements at 500°–600°; and concluded that J. L. Gay Lussac and L. J. Thénard's nitride was a mixture derived from impurities in the sodium, and from the action of sodium on the glass during their preparation of the amide. J. L. Gay Lussac and L. J. Thénard found that potassium amide decomposes when heated; and A. W. Titherley noted that the colour of the

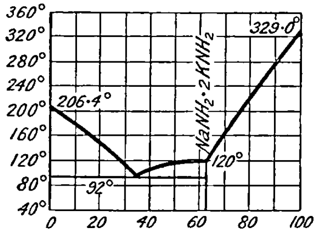

FIG. 50.—The Freezing Points of Mixtures of Potassium and Sodium Amides.

molten amide darkens with rise of temp. being almost black at 500°. A. W. Titherley said that the amide decomposes only when heated in glass vessels; in silver vessels the amide begins to sublime at 400°, and it distils rapidly in a current of hydrogen at 400°–500°. The product of the decomposition is not K_3N, but the amide is resolved into its elements. Rubidium amide melts to a greenish-brown viscid liquid, and becomes darker in colour as the temp. rises. The brown liquid distils at 400°. R. de Forcrand gave for the heat of formation $NH_{3gas}+Na_{solid}=H_{gas}+NaNH_{2solid}+20·84$ Cals.; with liquid ammonia, 16 Cals.; and $NaNH_{3solid}=H_{gas}+NaNH_2+15·64$ Cals. The heat of soln. at 20°–22° is 31·04 Cals. A. Guntz and F. Benoit gave 86·70 Cals. for the heat of formation of lithium amide, $LiNH_2$. H. Davy said the alkali amide is a non-conductor of electricity. J. M. McGee said that while sodamide melts at 208°, it has a sp. conductivity of 1·665 mhos at 210°—above this temp. the platinum electrodes act catalytically in the decomposition of sodamide into ammonia and sodium imide or nitride. According to L. Wöhler and F. Stang-Lund, molten sodamide or potassamide conducts a current electrolytically, due to the ionization $NaNH_2=Na^{\cdot}+NH'_2$. Hydrazine is not formed at the anode, but rather ammonia and nitrogen, the discharge of the anion taking place according to the equation $6NH'_2+6\oplus=4NH_3+N_2$. The formation of hydrazine was probably prevented by the catalytic action of the sodamide. The sp. conductivity at 210° is 0·593 mho for sodamide; and at 340°, 0·389 mho for potassamide. The decomposition voltage at the m.p. is 0·71 volt for sodamide and 0·87 volt for potassamide, the former having a temp. coeff. of $1·52\times10^{-3}$ volt. E. C. Franklin and C. A. Kraus studied the electrical conductivity of sodium amide in liquid ammonia.

When kept in dry stoppered bottles, sodamide gradually changes in colour from white to yellowish-brown owing to the formation of oxidation products—hyponitrites, nitrites, etc.—since no change occurs if the amide be well protected from air. According to E. Drechsel, if exposed to air, the amide acquires a crust of nitrite. Sodium amide is hygroscopic and readily decomposes when exposed to moist air. F. W. Bergstrom said that the elements react with soln. of amides in liquid ammonia provided that the salts of the element are soluble in ammonia: $M+nA(NH_2)\rightleftharpoons nA+M(NH_2)_n$, where M represents a metal of valency n, and A the alkali metal. This agrees with E. C. Franklin's statement that potassium amide in liquid ammonia is a base like potassium hydroxide is in water. A. W. Titherley found that sodium amide does not react to any appreciable extent when heated with **hydrogen** in a closed vessel; but F. D. Miles showed that sodium hydride is formed when the amide is heated between 200° and 300° in a stream of hydrogen: $NaNH_2+H_2=NH_3+NaH$. A. Guntz and F. Benoit studied the reaction. J. L. Gay Lussac and L. J. Thénard, and H. Davy found that when potassium amide is heated in **oxygen,** or **air,** there is a vigorous combustion and nitrogen is set free and potassium hydroxide is formed. E. Rengade said that when oxygen is passed into a soln. of potassium amide in liquid ammonia the main reaction is: $2KNH_2+3O=KNO_2+KOH+NH_3$—a little nitrate is produced. Cæsium amide acts similarly. H. Schrader found that when the alkali amides are exposed to air, they undergo autoxidation with formation of nitrite, hydroxide, and ammonia. When finely-divided sodamide is exposed to air in presence of a little water, a yellowish-red product is formed, which has now been shown to be **sodium amidoperoxide,** probably of the formula $NaNH_2O_2$. After 58 days, a sample was found to contain 0·44 molar per cent. of peroxide and 6·9 mols. per cent. of nitrite calculated on the sodamide taken. In dry air autoxidation does not take place at the ordinary temp., but at 100°–110° C. it proceeds slowly, 9·5 mols. per cent. of peroxide being formed in the course of 170 hrs. The peroxide is stable in dry air, but in moist air is changed into a white substance, the aq. soln. of which gives the peroxide reaction. J. L. Gay Lussac and L. J. Thénard, and H. Davy showed that potassium amide reacts vigorously with **water,** forming potassium hydroxide; the reaction may be accompanied by inflammation. If an excess of water be avoided, ammonia eq. to the nitrogen present is evolved; no hydrogen is formed unless the free metal be present. L. Wöhler and F. Stang-Lund said that the reaction with water is more regular if the amide be previously moistened with alcohol. E. Rengade said that the reaction with cæsium amide and water in air proceeds with incandescence; and without air, $CsNH_2+H_2O=CsOH+NH_3$. According to W. P. Winter, when sodium amide is treated with water, it behaves not unlike sodium, since it forms a globule which floats about on the water and at last explodes—sodium hydroxide and ammonia soluble in water are produced: $NaNH_2+H_2O \rightarrow NaOH+NH_3$; while hydrogen and a little free nitrogen are formed as secondary products of the reaction. The proportion of nitrogen to hydrogen is lower if the sodamide has been made at a relatively low temp., and the proportion increases when the sodamide has been kept for some time so that hydrogen is completely eliminated by preparing the compound at a high temp. or by keeping it a long time in closed bottles.

When heated with the **halogens**, sodamide does not decompose $2NaNH_2+Br_2 \rightarrow 2NaBr+NH_2.NH_2$, but rather decomposes $4NaNH_2+3Br_2 \rightarrow 4NaBr+N_2+2NH_4Br$—*vide infra*, preparation of hydrazine. L. Wöhler and F. Stang-Lund observed that chlorine and iodine do not form hydrazine with the amides, but halogen-substituted ammonias. F. Ephraim said that a soln. of bromine or iodine in benzene develops nitrogen and forms sodium and ammonium halide, but no hydrazine. O. Ruff said that when a soln. of the amide in liquid ammonia is treated with iodine, Na_2NI_3 is formed. F. W. Bergstrom represented the reaction with iodine at $-33°$, $6I+6NaNH_2=6NaI+4NH_3+N_2$. Dil. **hydrochloric acid** furnishes sodium and ammonium chlorides. F. Ephraim found that sodium amide reacts energetically with molten **sulphur**, and a soln. of sulphur in benzene or xylene forms nitrogen, ammonia, and sodium polysulphides. F. W. Bergstrom found that sulphur readily reacts with the amides; while with selenium at $-33°$ or at ordinary temp., there is first formed a white precipitate containing an explosive substance; an excess of **selenium** then yields highly coloured soln. containing polyselenides and a soluble, non-explosive potassium salt of an ammino-acid of this element. At $-33°$, **tellurium** reacts slowly with potassium and sodium amides, but rapidly at ordinary temp. H. Schumann observed a lively reaction between **sulphur dioxide** and potassium amide at 200°, forming $(NH_3)_2SO_2$ and $(NH_3)SO_2$, which sublime, and a mixture containing potassium, sulphur dioxide, and ammonia remains.

H. Krüger and E. Drechsel observed that sodium cyanide is formed when a mixture of sodium amide and **carbon** is heated. F. Beilstein and A. Geuther showed that with **carbon monoxide,** sodamide forms sodium cyanide, $NaNH_2+CO=NaCN+H_2O$; with **carbon dioxide,** it is supposed that sodium carbamate, $CO(NH_2)ONa$, is first formed: $CO_2+NaNH_2 \rightarrow H_2N.CO.ONa$; and this when heated forms sodium cyanate, NaOCN, thus: $NH_2.CO.ONa \rightarrow H_2O+NaOCN$, and disodium cyanamide, $CN.N:Na_2$ is then formed: $NaOCN+NaNH_2 \rightarrow H_2O+CN.N:Na_2$; the complete reaction is represented: $2NaNH_2+CO_2 \rightarrow 2H_2O+CN.N:Na_2$. The reaction is complicated by the presence of moisture. W. P. Winter found that warm water containing carbon dioxide in soln. forms some cyanamide in contact with sodium amide. With **carbon disulphide,** sodamide forms sodium thiocyanate: $NaNH_2+CS_2 \rightarrow H_2S+NaCNS$; and with **carbonyl chloride,** not urea, but a mixture of sodium carbonate and chloride is formed. F. Rössler observed that sodium amide at 120° reacts vigorously with **benzene, alcohol, acetylene,** etc., forming sodium cyanamide, useful as a manure or for the manufacture of sodium cyanide. When heated with **alkyl iodides,** a very small proportion of the corresponding alkylamine is formed, *e.g.* with ethyl iodide, $C_2H_5I+NH_2Na \rightarrow NaI+C_2H_5NH_2$; the main reaction results in the formation of carbon, iodine, etc. Sodamide in the presence of substances capable of reacting with it breaks down in two ways: (i) The rupture of the mol. may occur between the sodium and the amido- or NH_2-group as is the case when it reacts with water;

and (ii) The hydrogen atoms of the amido-group may be replaced one at a time by other radicles, as is the case when sodamide is treated with a boiling soln. of **aniline,** $C_6H_5.NH_2$, in benzene, sodium aniline—*i.e. sodium phenylamide,* $C_6H_5.NH.Na$, is formed; and when a mixture of diphenylamide, $(C_6H_5)_2NH$, and sodamide is heated to about 55°, a rapid action occurs, and sodium diphenylamide is formed: $(C_6H_5)_2N.Na$. A. W. Titherley found that when sodium amide mixed with **silica** is heated to 300°–400°, silicon nitride is formed; **glass** is attacked; and with **boric oxide,** boron nitride is formed; $2NaNH_2+B_2O_3=2BN+2NaOH+H_2O$; **lead borate** is reduced to lead. J. M. McGee said that the solvent action on glass observed by A. W. Titherley was really due to the presence of sodium hydroxide, since no tendency to attack glass was observed below 240°, but at 270°–300°, there is a slight action in 2 or 3 days.

W. Wislicenus showed that with **nitrous oxide** at 150°–250°, sodium azide is formed. A. W. Titherley found that when sodium amide is warmed with **nitrosyl chloride,** nitrogen is evolved: $NOCl+NaNH_2 \rightarrow NaCl+N_2+H_2O$. E. Rengade said that sodium amide is insoluble in liquid **ammonia;** but potassium amide dissolves; and cæsium amide is sparingly soluble. A. W. Browne and F. Wilcoxon found that **sodium nitrate** is ammonolyzed by fused sodamide: $NaNO_3+3NaNH_2=NaN_3+3NaOH+NH_3$; and E. C. Franklin, by warming a mixture of sodium nitrate and amide in liquid ammonia in a sealed tube. W. P. Winter found that yellow **phosphorus** reacts with sodium amide, forming sodium phosphide and other products; F. W. Bergstrom found that red and yellow phosphorus react with potassamide. W. P. Winter observed that the amide also reacts vigorously with **phosphorus pentachloride,** forming a complex series of products of unknown composition. F. W. Bergstrom found that **arsenic** and **antimony** react at ordinary temp. with potassium amide, while the reaction with **bismuth** is very slow. F. Ephraim observed that **arsenic trioxide** is reduced partly to the metal, and sodium arsenite is formed; **antimony trioxide** behaves in an analogous manner.

A. W. Titherley reported that a soln. of **sodium** in sodamide is blue, but J. M. McGee could not make it. According to F. Ephraim, when sodium amide and **magnesium** are heated together, magnesium nitride and sodium are formed. Sodium amide does not react with **iron, tin, copper,** and **silver.** According to F. W. Bergstrom, ammonia soln. of potassium or sodium amide form red soln. with tin: $10Sn+6MNH_2=M_4Sn_8+2SnNM(NH_3)_2$. In the more conc. soln. of potassamide, the formation over the metal of a passive coating, removable by ammonium chloride, prevents reaction. The curves of solubility of tin in the amides plotted against conc. indicate the formation of the compounds Na_4Sn_8 or K_4Sn_8, respectively. **Lead** behaved towards potassamide in an erratic manner; either a green soln. containing polyplumbide and, presumably, ammonioplumbite was slowly formed or there was no action, as was the case with sodamide. A soln. of potassamide (0·6*N*) did not attack **gold,** copper, or **germanium,** and **mercury** was attacked with extreme slowness. Amalgams of lead, bismuth, or silver were unaffected; those of copper and gold were attacked very slowly, and that of tin more rapidly. F. Ephraim found that when sodium amide is heated with **ammonium chloride or iodide,** sodium chloride or iodide is produced. It reacts generally as a reducing agent, thus, the **chlorides of lead, mercury, silver, tin, zinc, and barium** are reduced to the metals; **calcium and potassium chlorides** are not reduced. A. W. Titherley observed no reaction between the amide and **sodium or potassium oxide.** The **oxides of lead, copper, and cadmium** are reduced to metals; **zinc oxide** probably forms zinc nitride; **mercuric oxide** forms sodium amalgam; **chromic anhydride** reacts vigorously when rubbed in a mortar with sodium amide; **chromic oxide** when heated with the amide forms a black substance; **ferric oxide** furnishes iron; **manganese oxide** is not reduced to metal; **tungstic oxide** reacts with incandescence; **vanadium pentoxide** reacts vigorously when heated with sodium amide, and sodium vanadate is formed. Many of the **nitrates** deflagrate when triturated with sodamide, and a mixture of sodamide with **potassium chlorate** explodes. Sodium amide does not easily reduce **sodium chromate.** The **sulphides** of the heavy metals mixed with powdered sodium amide and heated are reduced to the metals; **antimony and arsenic trisulphides** give sulphosalts. The **sulphates** are reduced to sulphides and then to the metals; the **phosphates** are not reduced to phosphides, but to the metal. The alkaline earth phosphates are not reduced. A. W. Titherley found that lithium and rubidium amides react very like sodium amide. J. A. Joannis prepared a complex salt, sodium chloroamide, $NaNH_2.NaCl$, by the action of liquid ammonia on a mixture of sodium and sodium chloride. F. W. Bergstrom studied the action of potassamide in liquid ammonia soln. on **manganese, cobalt and iron salts.**

According to F. W. Dafert and R. Miklauz, when lithium nitride is heated at 220°–250° in a current of hydrogen, **lithium tritammonium,** Li_3NH_4, is formed as a hygroscopic substance which evolves hydrogen and ammonia when treated with water. O. Ruff and H. Georges said that it is a mixture of a mol of lithium amide and 2 mols of lithium hydride being formed in accord with $Li_3N+2H_2=LiNH_2+2LiH$. The resulting mixture of amide and hydride at 340°–480° gives lithiumimide and ammonia, from the decomposition of the amide, and the ammonia immediately combines with the hydride, forming imide and hydrogen, so that the total reaction is given by the equation: $2LiNH_2+4LiH=2Li_2NH+2LiH+2H_2$. This is supported by the fact that lithium amide does decompose into the imide and ammonia at 240°–450°, and that at a slightly higher temperature lithium hydride reacts with ammonia with the formation of lithium amide. F. W. Dafert and R. Miklauz based their hypothesis that lithium tritammonium is a chemical individual on the facts: (i) Lithium imide is easily decomposed on exposure to sunlight, according to the equation: $2Li_2NH=Li_3N+LiNH_2$, at the same time becoming coloured intensely red as shown by R. C. Mentrel. Trilithium amide is not sensitive to sunlight and therefore cannot be a mixture of lithium imide and lithium hydride; (ii) the conversion of Li_3NH_4 into Li_3NH_2 is a reversible process; (iii) analogy with tricalcium amide is not in favour of trilithium amide being a mixture of lithium amide and hydride. When the alleged lithium tritammonium is heated to 480°, **lithium tritamide,** Li_3NH_2, is formed. It possesses properties analogous to those of the triammonium compound. Lithium tritamide is also formed directly by the action of hydrogen on crystallized lithium nitride which has been obtained by heating lithium at 460° in a current of nitrogen; the reaction is so vigorous that the amide is obtained as a fused mass. When the tritamide is exposed to sunlight, a red substance, thought to be **lithium imide,** Li_2NH, is formed: $Li_3NH_2=Li_2NH+LiH$. Lithium tritamide, at about 600°, reacts with nitrogen, forming the imide: $4Li_3NH_2+N_2=6Li_2NH+H_2$. A. Guntz and F. Benoit gave 52·6 Cals. for the heat of formation of lithium imide.

E. C. Franklin prepared **rubidium diamidolithiate,** $Rb[Li(NH_2)_2]$, or $LiNH_2.RbNH_2$; **rubidium diamidosodiate,** $Rb[Na(NH_2)_2]$, or $NaNH_2.RbNH_2$; **rubidium triamidosodiate,** $Rb_2[Na(NH_2)_3]$; **potassium triamidolithiate,** $K_2[Li(NH_2)_3]$; and **potassium triamidosodiate,** $K_2[Na(NH_2)]_3$. As indicated above, lithium imide was reported by R. C. Mentrel to be formed by heating lithium amide to 450° in vacuo; but it is not formed by heating lithium and lithium amide in vacuo at 460°. O. Ruff and H. Georges obtained the imide by heating the amide in a silver dish at 360° until the evolution of ammonia had almost ceased, and then raising the temp. to 450°. It forms a white, partly-sintered mass of sp. gr. 1·303 at 19°; and it does not melt at 600°, but assumes a yellow colour—the white colour is restored on cooling. At higher temp., it decomposes, giving the blue lithium ammonia compound and a white powder—possibly lithium nitride. F. W. Dafert and R. Miklauz observed that on exposure to sunlight, lithium imide decomposes according to the equation: $2Li_2NH=Li_3N+LiNH_2$, the reaction being accompanied by the development of a dark red colour. At 450°, lithium imide reacts with hydrogen, forming the tritamide: $3Li_2NH+2H_2=2Li_3NH_2+NH_3$.

Attempts by A. W. Titherley to make **sodium imide,** Na_2NH, by the action of ammonia on sodium oxide gave sodamide, $NaNH_2$, and water: $Na_2O+2NH_3 \rightarrow 2NaNH_2+H_2O$. The water at once decomposes the sodamide, forming sodium hydroxide and ammonia, but if the action be suddenly stopped some of the primary product—sodamide—can be obtained; sodium oxide and sodamide do not react to any appreciable extent. See potassium and sodium amides for the properties.

F. F. Fitzgerald[3] treated a soln. of copper tetramminonitrate with potassium amide, and washed the olive-green precipitate. The product is thought to be **cuprous amide.** It is soluble in an excess of the alkali amide. E. C. Franklin treated cuprous nitride with a soln. of potassium amide in liquid ammonia, and obtained **cuprous hemipentamminopotassioamide,** $CuNK_2.2\frac{1}{2}NH_3$, or potassium ammoniocuprite, in colourless crystals which readily form **cuprous potassium amminoamide,** $CuNK_2.NH_3$, when heated below 200°, and at 200° form **cuprous potassium amide,** $CuNK_2$, or **potassium triamidocuprite,** $CuNK_2.2NH_3$ or $Cu(NH_2).2KNH_2$ or $K_2[Cu(NH_2)_3]$. E. C. Franklin mixed soln. of potassium amide and silver nitrate or iodide in liquid ammonia, and obtained a white precipitate of **silver amide,** $AgNH_2$. The compound is very explosive; it blackens in light; and is soluble in soln. of ammonium salts or of potassium amide in liquid ammonia, but not in the corresponding soln. of silver nitrate. J. Eggert showed that the sensitiveness of silver amide to explosion is not materially changed by lowering the temp. to —190°. A gradual isothermal change of press. to 5000 atm. brings about a decomposition of 97 per cent. of the samples of silver amide. E. C. Franklin found that **silver potassium amide,** $AgNHK.NH_3$, or $AgNH_2.KNH_2$, or $K[Ag(NH_2)_2]$, **potassium amidoargentate,** $AgNH_2+KNH_2=NH_3+AgNHK$, separates in crystals from conc. soln. of silver and potassium amides in liquid ammonia. These can be heated at 100° without change, but gradually undergo decomposition when left in the air. If the salt is treated with soln. of acids in liquid ammonia, silver amide is first precipitated, and dissolves, on further addition of the acid, with formation of the silver salt of the acid used. For **silver imide,** Ag_2NH, *vide* fulminating silver—**3.** 22, 11. According to J. Jacobsen, when silver nitrate is added to a soln. of chloroauric acid, a brown precipitate is obtained according to the equation $HAuCl_4+4AgNO_3+3H_2O=Au(OH)_3,4AgCl+4HNO_3$. By the action of ammonia, this is converted into fulminating gold, or **auric dihydroxyamide,** $Au(OH)_2.NH_2$, or $(AuN,2H_2O),H_2O$. The substance, when washed with aq. ammonia, followed by water, alcohol, and ether, and dried at a low temp., explodes violently when touched with a knife. The explosion takes effect in a downward direction. On boiling fulminating gold with potassium hydroxide, blackish-brown, flocculent, explosive, **auric tetrahydroxyimide,** $Au(OH)_2.NH.Au(OH)_2$, is formed. For F. Raschig's **auric imidoamide,** $NH : Au.NH_2$, and **auric chloroimide,** $NH : AuCl$, *vide* fulminating gold—**3.** 23, 14.

H. Moissan[4] prepared **calcium amide,** $Ca(NH_2)_2$, in transparent crystals, by the spontaneous decomposition of calcium ammine in an atm. of ammonia, or in a sealed tube. G. Roederer obtained white **strontium amide,** $Sr(NH_2)_2$, by heating the hexammine in vacuo at 50°, or by heating strontium in gaseous ammonia at 200°; at a higher temp., say 800°, only the hydride and nitride are formed. The Badische Anilin- und Soda-fabrik passed ammonia into soln. of the alkaline earth metals in fused, anhydrous alkali hydroxide. J. A. Joannis obtained **barium amide,** $Ba(NH_2)_2$, by allowing a mixture of barium bromide, potassium, and an excess of liquid ammonia to stand for some days; $BaBr_2+2KNH_3=2KBr+H_2+Ba(NH_2)_2$; H. Moissan, by the action of ammonia on barium hydride: $BaH_2+2NH_3=2H_2+Ba(NH_2)_2$; A. Guntz and R. C. Mentrel, by heating barium at 280°–400° in a stream of ammonia—above 460°, barium nitride is formed; and R. C. Mentrel, by warming barium hexammine—the reaction is slow at 0°, fast at 30°, and very rapid at 60°; and the reaction also proceeds more quickly in vacuo. The greyish-white barium amide is decomposed by moist air and by water. A. Guntz gave for the heat of formation: $Ba+2NH_3=Ba(NH_2)_2+H_2+53{\cdot}3$ Cals. For the properties, see the alkali amides.

According to F. W. Dafert and R. Miklauz, when a mixture of equal vols. of hydrogen and nitrogen is passed over the heated alkaline earth metals, or over their hydrides or nitrides, as the case may be, **calcium imide,** $CaNH$, **strontium imide,** $SrNH$, or **barium imide,** $BaNH$, is produced. These compounds darken on exposure to light as in the case of lithium imide. Calcium imide is the most easily prepared, but it has not been obtained pure ; while the formation of barium imide is incomplete. A. Guntz and F. Benoit gave 80·24 Cals. for the heat of formation of barium amide ; 84·3 Cals., for strontium amide ; 93·0 Cals., for calcium amide ; and for barium imide, $BaNH$, 54·4 Cals. E. C. Franklin prepared **potassium amidobariate,** $BaNK.2NH_3$, or $Ba(NH_2)_2KNH_2$, or $K[Ba(NH_2]_3]$, by the action of an excess of a barium salt on potassium amide, in liquid ammonia soln.; **potassium triamidocalciate,** $K[Ca(NH_2)_3]$, or $CaNK.2NH_3$; and **potassium diamidostrontiate,** $SrNK.2NH_3$, or $K[Sr(NH_2)_3]$, were made in a similar way.

According to F. W. Dafert and R. Miklauz, when calcium nitride is heated, within certain limits of temp., in a stream of hydrogen, the gas is absorbed, forming lemon-yellow or orange-yellow **calcium tritadiamide,** $Ca_3(NH_2)_2$, which is scarcely affected by heating in nitrogen or hydrogen, but changes slowly in diffused light, and rapidly in sunlight, to a greyish-black substance, probably a mixture of calcium imide and calcium hydride, formed according to the equation $Ca_3(NH_2)_2=2CaNH+CaH_2$. The amide, in an impure form, has also been prepared by heating calcium hydride in nitrogen. F. W. Dafert and R. Miklauz similarly obtained **strontium tritadiamide,** $Sr_3(NH_2)_2$, by the action of hydrogen on strontium nitride ; but **barium tritadiamide,** $Ba_3(NH_2)_2$, cannot be so obtained because it reacts with hydrogen. The temp. at which hydrogen and nitrogen unite with the metals and at which hydrogen unites with the nitride, are :

	Ca	Sr	Ba	Ca_3N_2	Sr_3N_2	Ba_3N_2
Nitrogen	410°	380°	260°	—	—	—
Hydrogen	300°	215°	170°	230°	270°	300°

This shows that the tendency of the alkaline-earth metals to combine with nitrogen and hydrogen increases with the at. wt., whilst the tendency of the nitrides to combine with hydrogen decreases with increase in at. wt. of the metal.

E. C. Franklin,[5] and F. W. Bergstrom prepared **magnesium amide,** $Mg(NH_2)_2$, by the action of magnesium on a soln. of the alkali metals in liquid ammonia; of sodium or potassium ammonomagnesiates on magnesium and liquid ammonia; and of lithium or sodium amide and magnesium on a soln. of sodium in liquid ammonia. F. W. Bergstrom obtained **magnesium diamminosodamide,** $Mg(NHNa)_2.2NH_3$, or $Na_2[Mg(NH_2)_4]$. He prepared **magnesium diamminopotassamide,** $Mg(NHK)_2.2NH_3$, or *potassium ammonomagnesiate*, by the action of potassium amide in liquid ammonia soln. on magnesium: $Mg+2KNH_2+2NH_3=H_2+Mg(NHK)_2.2NH_3$; or on magnesium iodide, nitrate, or acetamide: $MgI_2+4KNH_2=Mg(NHK)_2.2NH_3+2KI$. The salt occurs as a fine, crystalline powder, which is only slightly soluble in liquid ammonia, and is rapidly hydrolyzed by liquid water or water vapour. It is not explosive, and may be heated to 100° without loss of ammonia. For the properties, see the alkali amides. E. Frankland passed ammonia into an ethereal soln. of zinc ethyl, and obtained **zinc amide,** $Zn(NH_2)_2$, and ethane: $Zn(C_2H_5)_2+2NH_3=Zn(NH_2)_2+2C_2H_6$. The white, amorphous solid is not decomposed at 200° ; it is insoluble in ether ; and is decomposed by water : $Zn(NH_2)_2+2H_2O=2NH_3+Zn(OH)_2$. H. Peltzer said that with dry hydrogen chloride, ammonium tetrachlorozincate, $(NH_4)_2.ZnCl_4$, is formed. F. F. Fitzgerald, and E. C. Franklin prepared **zinc potassamide,** or **potassium tetramidozincate,** $K[Zn(NH_2)_4]$, $2KNH_2Zn(NH)_2$, or $Zn(NHK)_2.2NH_3$, by the action of a soln. of potassium amide in liquid ammonia on powdered zinc, zinc amide, or zinc tetramminoiodide for 7 days: $Zn(NH_3)_4I_2+4KNH_2$

$=Zn(NHK)_2.2NH_3+2KI+4NH_3$. The colourless crystals decompose on exposure to air; they react vigorously with water, forming ammonia, and zinc and potassium hydroxides; they are sparingly soluble in liquid ammonia, but soluble in soln. of ammonium salts in liquid ammonia; they dissolve energetically in dil. acids with the evolution of much heat; and they are not decomposed when heated to 160° in vacuo, but at a higher temp., they give off ammonia. If heated to 220°, **zinc amminopotassamide,** $Zn(NHK)_2.NH_3$, or $Zn(NH_2)_2.K_2NH$, **zinc potassium imidoamide,** is formed; and at 250°–325°, **zinc hemiamminopotassamide,** $Zn(NHK).\frac{1}{2}NH_3$, or potassium ammoniozincate. G. S. Bohart found that when cadmium iodide, or potassium cadmium cyanide, is treated with a soln. of potassamide in liquid ammonia, cadmium amide or potassium cadmium amide is formed according as the ammonio-base or the salt is in excess. **Cadmium amide,** $Cd(NH_2)_2$, is a white powder, which on exposure to moist air assumes an orange colour, and then slowly changes to pure, white cadmium hydroxide. It reacts violently with water, and when suddenly heated explodes with the liberation of metallic cadmium. When heated at 180° in vacuo, it loses ammonia and leaves cadmium nitride, Cd_3N_2, a black, amorphous powder, which becomes orange-coloured on exposure to moist air, and then slowly becomes white. It explodes violently when brought into contact with water, and deposits metallic cadmium. **Cadmium potassamide,** or *potassium cadmium amide,* $Cd(NHK)_2,2NH_3$, or **potassium tetramido-cadmiate,** $K[Cd(NH_2)_4]$, is a white, flocculent powder, which becomes grey when exposed to light. It reacts violently with water, producing ammonia, potassium hydroxide, and cadmium hydroxide. E. C. Franklin prepared **cadmium diamminopotassamide,** $Cd(NHK)_2.2NH_3$, *potassium ammoniocadmiate,* by adding potassium amide to a soln. of cadmium iodide or nitrate in liquid ammonia. For *mercury amide,* $Hg(NH_2)_2$; *mercury imide,* HgNH, and various derivatives—*vide* **4.** 31, 8 *et seq.* O. Ruff and E. Geisel found that soln. of mercuric iodide and nitrogen sulphide reacted in liquid ammonia soln., forming a precipitate of **mercuric thiodiimide,** $HgN_2S.NH_3$, in bright yellow crystals which resemble the lead compound, but contains one atom of sulphur less. The addition of lead iodide to the filtrate from the mercury compound produces a precipitate of lead dithiodi-imide, and, conversely, mercuric iodide precipitates mercury thiodi-imide from the filtrate from the lead compound. H. Hirzel obtained **mercurous amidoarsenate,** $Hg_2(NH_2)AsO_4$, by boiling mercuric oxide with a soln. of ammonium arsenate. The white compound resembled the corresponding amidophosphate. E. C. Franklin represented its constitution $Hg : AsO_4.Hg.NH_2$.

J. A. Joannis[6] prepared **boron amide** or **boramide,** $B(NH_2)_3$, by the action of ammonia on boron trichloride, at —23°: $BCl_3+15NH_3=3NH_4(NH_3)_3Cl+B(NH_2)_3$; and at 0°: $BCl_3+6NH_3=3NH_4Cl+B(NH_2)_3$. If the temp. be higher than this, the amide passes into the imide. The removal of the ammonium chloride by washing with liquid ammonia is attended by great losses. The preparation of **boron imide** or **borimide,** $B_2(NH)_3$, was effected by J. A. Joannis as just indicated, or by the action of ammonia on boron tribromide at 0°: $2BBr_3+27NH_3=6NH_4(NH_3)_3Br+B_2(NH)_3$. A. Stock and M. Blix made it by warming boron hexamminosulphide, $B_2S_3.6NH_3$, for many hours, at 115°–120°, in a current of dry hydrogen or ammonia: $B_2S_3.6NH_3=3NH_4SH+B_2(NH)_3$. The product is contaminated with a little sulphur, and in order to keep the amount small, the imide is powdered and treated with ammonia for a day at 115°. The white powder begins to give off ammonia above 125°, and at higher temp., the nitride is formed quantitatively: $B_2(NH)_3=2BN+NH_3$. The imide is insoluble in alcohol, ether, carbon disulphide, and liquid ammonia; no solvent is known which does not decompose the imide. Water decomposes it with the evolution of heat, forming boric acid and ammonia. The imide reacts with hydrogen chloride with the evolution of heat and the formation of **boron imidohydrochloride,** $B_2(NH)_3.3HCl$. After shaking boron imide for 12 hrs. with liquid ammonia, the imide increases in vol. and some amide is formed; if sulphur be mixed with the liquid ammonia, the imide, at 100°, acquires a dark blue colour, and on evaporation, an amorphous substance is formed which imparts to water a violet colour ; acids cause the separation of milk of sulphur.

F. W. Bergstrom [7] found that amalgamated aluminium reacts with sodamide in liquid ammonia soln., forming crystalline **sodium aluminium amide,** or *sodium ammonaluminate,* or *sodium amidoaluminate,* to which one of the following formulæ is applicable: $Al(NH_2)_2.NHNa.NH_3$; or $Al(NH_2)_3.NaNH_2$; or $Na[Al(NH_2)_4]$. The reactions are supposed to be $Al+3NaNH_2 \rightleftharpoons Al(NH_2)_3+3Na$; $Al(NH_2)_3+NaNH_2 = Al(NH_2)_2NHNa.NH_3$; and $3Na+3NH_3=\frac{3}{2}H_2+3NaNH_2$. This compound loses a mol of ammonia when heated in vacuo above 90°. The reaction with potassamide, forming **potassium aluminium amide,** $Al(NH_2)_2.NHK.NH_3$, or $Al(NH_2)_3.KNH_2$, is similar. It is assumed that dil. soln. of the alkali metals in ammonia are salt-like in character. If the product be dried in vacuo at 80°–115°, there remains potassium aluminium amide, $Al(NH_2)_2.KNH$. E. C. Franklin found that when an excess of aluminium iodide is added to a soln. of potassium amide in liquid ammonia, a white precipitate is produced which is redissolved by an excess of potassium amide; on the addition of potassium amide in quantity just sufficient to yield a permanent precipitate, **aluminium iodoamide,** or *ammoniobasic aluminium iodide,* is formed: $2AlI_3+3KNH_2 = 3KI+Al(NH_2)_3.AlI_3$. At ordinary temp., this salt separates from the soln. as a crystalline *hexammine,* $Al(NH_2)_3.AlI_3.6NH_3$; and at low temp., as an *octodecammine.* If potassium amide be added to a soln. of this salt in liquid ammonia, the composition of the precipitated salt is $Al(NH_2)_3.Al(NH_2)I.NH_3$; and when heated, it loses 2 mols of ammonia, forming $Al(NH_2)_3.AlNHI$, **aluminium iodoimidoamide.**

E. C. Franklin showed that if potassium amide acts on black thallium nitride in liquid ammonia, **thallous tetramminopotassioamide,** $TlNK_2.4NH_3$, or $TlNH_2.2KNH_2.2NH_3$, *potassium triamidothallite,* $K_2[Tl(NH_2)_3]$, is formed in golden-yellow crystals freed from excess of ammonia in vacuo at —40°. It loses 2 mols of ammonia at 20° in vacuo forming $TlNK_2.2NH_3$, or $TlNH_2.2KNH_2$; and at 100°, another $\frac{2}{3}$ mol, forming $TlNK_2.1\frac{1}{3}NH_3$, or $Tl_3N.6KNH_2$, or a mixture $Tl_3N+6KNH_2$. The crystals of the tetrammine are isomorphous with those of potassium amide, but *thallium amide and imide* are unknown in the free state, even at —33°. Both thallous nitride and the complex amides explode with great violence when subjected to shock, or heat, or when treated with water or dil. acids.

For *carbon amide,* see **2.** 20, 34. A. Stock and K. Somiesky [8] found that chlorosilane and ammonia gases react at ordinary temp., and if the former is in excess, ammonium chloride and **trimonosilylamine,** or **trisilylammonia,** $N(SiH_3)_3$, is formed as a spontaneously inflammable liquid: $3SiH_3Cl+4NH_3=(SiH_3)_3N+3NH_4Cl$. The vap. density agrees with the simple formula $N(SiH_3)_3$. The sp. gr. of the solid is 0·895 at —106° ; the b.p. is 52° ; and the m.p., —105·6°. The vap. press., p mm., is :

	—80°	—40°	—24·4°	—11·0°	—4·2°	0°	5°	10°	15°
p .	0·1	10	29	65	89	109	137	172	212

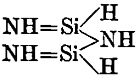
or $\log p = -1956·10T^{-1}+1·75 \log T - 0·00830T + 7·20404$. The liquid is stable in the absence of air ; it is vigorously decomposed by water: $N(SiH_3)_3+6H_2O = 3SiO_2+NH_3+9H_2$; it does not combine with hydrogen chloride or monochlorosilane ; but with hydrogen chloride: $(SiH_3)_3N+4HCl=3SiH_3Cl+NH_4Cl$. A homogeneous substance could not be isolated from the product of the action of monochlorosilane on an excess of ammonia. The chlorine is converted into ammonium chloride, and the silicon furnishes in the form of volatile compounds. The initial product is principally **disilylamine,** or **disilylammonia,** $NH(SiH_3)_2$, admixed with the tri- and mono- amines. The diamine is not stable in the dil. gaseous state, and slowly decomposes: $NH(SiH_3)_2=SiH_4+SiH_2:NH$, and the latter immediately condenses to the polymeric form $(SiH_2:NH)n$. The same product is obtained as a result of the reaction between dichlorosilane and an excess of ammonia: $SiH_2Cl_2+3NH_3=2NH_4Cl+SiH_2:NH$. The polymeride, $(SiH_2:NH)n$, is a white substance resembling silicic acid. The solid product in benzene soln. has n between 7 and 8. The residue obtained by evaporating the solvent is a viscid liquid which gradually passes into the solid—presumably a more highly polymerized condition. The polymeride is decomposed by a soln. of sodium hydroxide: $SiH_2:NH+2H_2O=SiO_2+2H_2+NH_3$, and the same change is more slowly produced by water; and with hydrogen chloride, $(SiH_3)_2NH+3HCl=2SiH_3Cl+NH_4Cl$. The behaviour towards gaseous hydrogen chloride is remarkable; mono-, di-, and tri-silylamines are smoothly and quantitatively transformed into monochlorosilane and ammonium chloride. The ready replaceability of the Si-N group by Si-halogen appears to be quite general with silicon compounds. In general, the compounds containing nitrogen exhibit a close analogy to the corresponding substances containing oxygen. Thus, the conversion of $NH_2.SiH_3$ into $NH(SiH_3)_2$ in the presence of an excess of ammonia is paralleled by the formation of $O(SiH_3)_2$, and not $SiH_3.OH$ by the action of an excess of water on monochlorosilane; the conversion of the volatile unimolecular SiH_2O into $(SiH_2O)x$ is similar to that of $SiH_2:NH$ into $(SiH_2:NH)x$, and affords a further example of the remarkable tendency towards polymerization of substances which contain but few hydrogen atoms directly united to silicon. O. Ruff and K. Albert prepared **silicon nitridihydride**, $H.Si:N$, by the action of ammonia on silicochloroform: $SiHCl_3+4NH_3=3NH_4Cl+SiHN$. O. Ruff found that the product is mixed with a little amide. On passing dry gaseous ammonia mixed with hydrogen into a Woulfe's bottle, cooled at 15°, into which silicochloroform diluted with hydrogen is simultaneously led, a white powder having the composition $N:SiH+3NH_4Cl+0{\cdot}2NH_3$ is obtained; the ammonium chloride may be almost completely removed by washing the product with liquefied ammonia in an apparatus from which moisture is excluded; but attempts to remove the ammonia completely, either at the ordinary temp. in a vacuum, or at 100°, cause partial decomposition according to the equation $SiNH+NH_3=Si(NH)_2+H_2$. The nitrohydride is a white powder with a caustic taste, which is decomposed by water or sodium hydroxide soln., giving hydrogen, thus: $SiHN+4NaOH=Si(ONa)_4+NH_3+H_2$; the action is quantitative. It has all the reducing properties of silicoformic anhydride, and is converted by dry hydrogen chloride at 300° into silicochloroform and ammonium chloride.

According to E. Lay, if a soln. of silicon tetrachloride in benzene be mixed with an emulsion of hydrazine in dry benzene, a white powder is obtained which is a mixture of crystals of hydrazine dichloride, and amorphous grains of a substance with the empirical composition, $Si(NH)_4$, or $Si(N_2H_2)_2$. A separation with organic solvents is not possible.

F. Lengfeld prepared **silicon tetramide**, $Si(NH_2)_4$, by the action of benzene soln. of silicon tetrachloride and ammonia, and subsequently evaporating the solvent. E. Vigouroux and C. Hugot allowed dry ammonia and silicon tetrachloride to react at −50°; much heat is developed. The ammonium chloride formed in the reaction is removed by washing the liquid ammonia on a glass-wool filter. Water decomposes the product with the evolution of ammonia. The white powder is stable below 0°; above that temp., ammonia is given off, and **silicon diimide**, $Si(NH)_2$, is formed. The diimide is formed by heating the tetramide at 120° or in vacuo at 100°. M. Blix made it by heating silicothiourea; some ammonium hydrosulphide is formed at the same time, but no free sulphur. M. Blix and W. Wirbelauer made it by the action of liquid ammonia on silicon disulphide, or silicon dichlorosulphide. In the latter case, the product is contaminated with some free sulphur. They also made it by treating silicon hexamminotetrachloride with liquid ammonia under press. The ammonium chloride was washed out with liquid ammonia. L. Gattermann employed a somewhat similar process. The white amorphous powder is stable even at the softening temp. of glass; but at a high temp., 900°, it is converted into silicam (*q.v.*). It is decomposed by moist air, and with water it furnishes silicic acid and ammonia. It does not furnish the amide when heated with ammonia. It forms salts with the halogen acids—*e.g.* liquid hydrogen chloride furnishes *silicon* *diimidodihydrochloride*, S.$(NH)_2.2HCl$. According to R. Schwarz and W. Sexauer, when a soln. of silicon hexachloride in anhydrous ether is gradually added to liquid ammonia, a polymer of **silicon diamidodiimide,** $NH_2.Si(NH).Si(NH).NH_2$, is formed, the accompanying ammonium chloride is removed by washing with liquid ammonia, and subsequently drying in a current of nitrogen at —20° to remove adsorbed ammonia. At about —10°, the compound loses ammonia, forming a polymer of **silicon triimide :**

$$\begin{array}{l} HN{=}Si \\ HN{=}Si \end{array}\!>NH$$

The triimide is stable at atm. temp. ; it decomposes above 400°, chiefly with the rupture of the silicon bridge, and the formation of some silicocyanogen, Si_2N_2. These compounds are very sensitive to oxygen, and particularly to moisture. A. Stock and F. Zeidler obtained **silicon dihydrotriimide :**



$$\begin{array}{l} NH{=}Si{<}^{H} \\ \quad\quad\quad >NH \\ NH{=}Si{<}_{H} \end{array}$$

by the action of ammonia on trichlorosilane under reduced press. and at ordinary temp., $2SiHCl_3+9NH_3=6NH_4Cl+[SiH(NH)]_2NH$. If the product be gradually heated it decomposes, mainly in accord with $[SiH(NH)]_2NH=2SiNH+NH_3$, and at about 250°, the ammonium chloride begins to sublime. The main action with hydrogen chloride is symbolized: $[SiH(NH)]_2NH+9HCl=2SiHCl_3+3NH_4Cl$. The action of ammonia on silicon tetrachloride furnishes **silicon imidodiamide,** $Si(NH_2)_2NH$, in accord with: $SiCl_4+7NH_3=4NH_4Cl+Si(NH_2)_2:NH$. M. Blix passed dry ammonia into a benzene soln. of silicon dibromosulphide, and obtained **silicon diamidosulphide,** $SiS(NH_2)_2$, or *silicon thiourea*, as a white powder which, after some time, decomposes: $SiS(NH_2)_2+2H_2O=SiO_2+H_2S+2NH_3$. It is decomposed by water into silicic acid, ammonia, and hydrogen sulphide. It has basic properties and forms salts with the halide acids. E. C. Franklin and T. B. Hine prepared **silicon potassioamidonitride,** $N{:}Si.NHK$, by the action of potassium amide, in liquid ammonia soln., on silicon amide.

A. W. Titherley obtained a brown powder by heating amorphous silica and alkali amide to 300°–400°. He regarded it as silicon imide. It was not decomposed by water or boiling alkali-lye; but with fused alkali-lye, ammonia is given off and alkali silicate formed.

M. Blix and W. Wirbelauer prepared **silicam,** or **silicon imidonitride,** Si_2N_3H, or NSi—NH—SiN, by heating silicon diimide to 900° in an atm. of dry nitrogen. Silicam was made in 1857, by H. St. C. Deville and F. Wöhler, by the action of ammonia on silicon tetrachloride. E. Lay made it by the action of dry ammonia on silicon hexamminotetrabromide, at 900°; an impure product is produced by heating it in hydrogen or nitrogen at 1000°. E. Lay found that the voluminous white powder so formed has no taste or smell; it has a sp. gr. of 2·015 at 17°; its colour is not changed by heating, but in the blue gas flame it slowly oxidizes with a greenish-yellow phosphorescence. The heat of formation is 132·44 Cals. When silicam is oxidized by heating it in *air*, nitrogen is evolved, but no apparent combustion occurs; in *oxygen*, however, combustion does occur with vivid incandescence—nitrogen and water are formed. If the oxygen be nascent—*e.g.* if the silicam be admixed with *lead dioxide; potassium chlorate, bromate, or nitrate; sodium dioxide; molybdic or chromic acid*—much of the nitrogen may be oxidized to nitrogen peroxide. Many oxides—*bismuth, cadmium, lead, copper, or mercury oxide*—are reduced when heated with silicam. M. Blix and W. Wirbelauer said that silicam is not decomposed by *water*, but E. Lay reported it to be slowly decomposed by water at ordinary temp., forming ammonia; with boiling water, the decomposition is rapid and complete. Boiling *alkali-lye* dissolves it, forming alkali silicate and ammonia; molten alkali hydroxide decomposes silicam very quickly.

Silicam is very stable towards the *halogens ;* with *chlorine* at a bright red-heat it forms hydrogen chloride. With *hydrofluoric acid,* silicam forms a clear soln. of ammonium fluosilicate. When heated with conc. *sulphuric acid,* ammonium sulphate is formed. When heated in a current of nitrogen at 1200°–1400°, it forms silicon nitride. Conc. *nitric acid* has no apparent action on silicam. When heated with *arsenic or antimony trioxide,* the metal and hydride are formed: $4As_2O_3+3Si_2N_3H=AsH_3+7As+6SiO_2+9N$. At a bright red-heat, silicam reduces *carbon dioxide* to carbon.

According to M. Blix and W. Wirbelauer, impure **titanium tetramide,** $Ti(NH_2)_4$, is produced by the action of liquid ammonia on titanium tetramminotetrachloride. A. Stähler obtained the same product by the action of liquid ammonia on the hexamminotetrachloride or octamminotetrachloride. The compound is vigorously decomposed by water. When the amide is heated, M. Blix and W. Wirbelauer say that **titanium diimide,** $Ti(NH)_2$, is probably formed. O. Ruff and F. Eisner said that the tetramide is always contaminated with chlorine, which on ignition furnishes hydrogen chloride, ammonium chloride, and **titanium chloronitride,** TiNCl. E. C. Franklin and T. B. Hine prepared **titanium potassioamidonitride,** $N:Ti.NHK$, by the action of potassium amide on titanium tetrabromide in liquid ammonia soln. The soln. probably contains the ammonolytic product **titanium bromonitride,** $N:TiBr$, which reacts: $N:TiBr+2KNH_2=KBr+NH_3+N:Ti.NHK$. The impure, brick-red powder is not explosive, but is vigorously decomposed by water. A. Stähler and B. Denk treated zirconium hexamminoiodide with liquid ammonia and obtained the octamminoiodide, which, when washed with liquid ammonia, decomposes into a mixture of **zirconium amide,** $Zr(NH_2)_4$, and ammonium iodide: $ZrI_4.8NH_3=4NH_4I+Zr(NH_2)_4$.

F. W. Bergstrom obtained **potassium stannous amide,** $Sn(NH_2)_2.KNH_2$, or $SnNK(NH_3)_2$, or $K[Sn(NH_2)_3]$, as a white solid, very soluble in liquid ammonia, by the action of mercury on the product of the reaction of tin with potassium amide; by the action of the amide on an excess of tin amalgam; or by the action of potassium amide on stannous chloride. The corresponding **sodium stannous amide,** $Sn(NH_2)_2.NaNH_2$, or $SnNaN(NH_3)_2$, or $Na[Sn(NH_3)_2]$, was obtained in a similar way. F. F. Fitzgerald found that when an excess of a soln. of potassamide in liquid ammonia is added to one of stannic iodide in the same solvent, a crystalline precipitate of **potassium stannic amide,** or *stannic tetramminopotassamide,* or *potassium hexamidostannate,* $K_2[Sn(NH_2)_6]$, or $Sn(NK)_2.4NH_3$, is produced, which, when heated at 145°, loses 3 mols. of ammonia. On further heating in a vacuum at 316°, a brick-red powder is obtained, which still contains some ammonia and is decomposed violently by water with evolution of gas and deposition of tin. E. C. Franklin showed that if a liquid ammonia soln. of potassium amide be treated with a soln. of lead iodide, an orange-red precipitate of **lead imide,** PbNH, is slowly formed. The colour slowly becomes brown. The compound explodes when heated, or when treated with water or dil. acids. It is dissolved by dil. acetic acid or dil. potash-lye. It is slowly decomposed by steam. If lead nitrate be used in place of the iodide, a basic salt, possibly $Pb_2N(NO_2)nNH_3$, is formed. With an excess of potassium amide a soluble **lead potassimide,** KPbN, is slowly formed. E. C. Franklin also made **potassium triamidoplumbite,** $K[Pb(NH_2)_3]$; and **lead iodoimidoamide,** $NH_2.PbNH.PbI$, or $Pb:N.PbI.NH_3$, or $PbNH.PbNH_2I$, by pouring potassium amide soln. on one of lead iodide and shaking the mixture as long as the lead iodide is in excess. The white, non-explosive precipitate, when heated, loses ammonia and gradually darkens in colour. Soln. of metal iodides in liquid ammonia were found by O. Ruff and E. Geisel to give precipitates with a liquid ammonia soln. of nitrogen sulphide; thus, lead iodide forms **lead dithiodiimide,** $PbN_2S_2.NH_3$, crystallizing in olive-green prisms, becoming orange in air without alteration of weight, decomposing when slowly heated, and exploding very violently at 140° when rapidly heated. Hydrogen chloride reacts quantitatively according to the equation $PbN_2S_2,NH_3+6HCl=PbCl_2+3NH_3+2S+4Cl$. Dry liquid hydrogen sulphide reacts thus: $PbN_2S_2,NH_3+3H_2S=PbS+4S+3NH_3$. Ethyl iodide forms ethyl sulphide and lead iodide. E. Chauvenet showed that when thorium tetramminotetrachloride is heated to 250°–300°, it forms **thorium amide,** $Th(NH_2)_4$, and at a red-heat, **thorium imide,** $Th(NH)_2$.

The amido- and imido-compounds of weak electronegative elements have not been prepared; no compounds of the NH_2-group with chromium, molybdenum, tungsten, and uranium are definitely known, but some more complex compounds of this type have been reported. R. J. Meyer and H. Best[9] obtained no evidence of the formation of **amidochromic acid,** $HO.CrO_2.NH_2$, by the action of ammonia on a soln. of potassium chlorochromate in dry acetone. E. Heintze prepared **potassium amidochromate,** $NH_2.CrO_2.OK$, by the action of dry ammonia on a soln. of potassium chlorochromate in dried ether free from alcohol. The aq. soln. of the salt furnishes red crystals which can be dried at 100°. J. Ohly also obtained it by the action of dry ammonia on potassium chlorochromate. A. Fock said that the monoclinic crystals have the axial ratios $a:b:c=1\cdot02832:1:1\cdot7751$. A cold, sat., aq. soln. contains 13 per cent. of the salt. If boiled for some hours with water, it is converted into a mixture of potassium and ammonium chromates; it reacts with nitrous acid: $2HNO_2+2K(NH_2)CrO_3=K_2Cr_2O_7+2N_2+3H_2O$; and when boiled with alkali-lye, ammonia is given off. Both G. Wyrouboff, and A. Werner and A. Klein were unable to prepare this compound by E. Heintze's method, and regard his product as impure potassium dichromate. S. Löwenthal prepared **ammonium amidochromate,** $(NH_4O)(NH_2)CrO$, by a process like that employed by E. Heintze for the potassium salt; and A. Fock described the monoclinic crystals. G. Wyrouboff, and A. Werner and A. Klein were unable to prepare the amidochromate, and G. Wyrouboff suggested that the alleged amidochromate is impure ammonium dichromate. S. Löwenthal obtained **lithium amidochromate,** $LiO.CrO_2.NH_2$, by the method employed for the potassium salt. A. Fock observed that the crystals are triclinic, but G. Wyrouboff could not obtain this compound when purified lithium salts were used. S. Löwenthal reported an impure **magnesium amidochromate,** and a **mercury amidochromate,** $Hg_3(CrO_3)_2NH_2$, formed by the action of potassium amidochromate on a soln. of mercuric acetate in conc. acetic acid. Some of the mercuriammonium chromates can be represented as amido-compounds. For the *amido-phosphates, vide* phosphorus. B. Skormin prepared **mercuric dioxydiamidochromate,** $3HgO.Hg(NH_2)_2.CrO_3$, or $Hg_4O_2(NH_2)_2CrO_4$, by the action of an excess of mercuric nitrate on ammonium chromate in a boiling soln.

A. Rosenheim and F. Jacobsohn treated freshly prepared potassium chlorochromate with liquid ammonia in a sealed tube. The product after washing with liquid ammonia corresponded with **potassium ammonium imidochromate,** $(NH_4)KCrO_3NH$, or $(KO)(NH_4O).CrO.NH$. When exposed to air, or when dissolved in water, ammonia is given off, and the ordinary chromate is formed. They also passed dry ammonia into a soln. of chromyl chloride in dry chloroform and obtained a brown voluminous mass with the composition $(NH_3)_3(CrO_2)_2(NH_4)_2$, which may be **ammonium triimidochromate,** $HN(NH.CrO.ONH_4)_2$. Most of the ammonium chloride can be washed away from the product by means of liquid ammonia. When chromic anhydride is treated with liquid ammonia in a sealed tube at ordinary temp., the product has the empirical composition $CrO_3.3NH_3$, but is thought to be **ammonium imidochromate,** $HN:CrO(ONH_4)_2$. The compound readily gives up ammonia to air, and dissolves in water to form ammonium dichromate. By the interaction of lead iodide, chromic anhydride, and liquid ammonia, **ammonium lead imidochromate,** $\{NH:CrO(ONH_4)O\}_2Pb$, is formed as a brown powder.

J. Ohly reported that he had made **chromyl amide,** or **chromium dioxyamide,** $CrO_2(NH_2)_2$, by dissolving potassium amidochromate in water; mixing with conc. aq. ammonia; covering the liquid with a layer of ether; and treating with chlorine. The brown soln. deposits leaflets of the alleged chromyl amide, which gives off ammonia when rubbed with soda-lime; and its aq. soln. gives the amido reactions with silver nitrate and lead acetate.

E. Uhrlaub prepared a substance with the composition $Mo_4N_{10}H_4$ and one with the composition $Mo_9N_{10}H_4$, by the action of dry ammonia on molybdenum chloride. The simpler formula *molybdenum imidonitride,* MoN_2H, may well apply. He also examined the action of dry ammonia on warm molybdenum trioxide, but the product was probably a mixture. The conclusions are therefore unsatisfactory. E. F. Smith and V. Lenher treated molybdenyl chloride, MoO_2Cl_2, with dry ammonia and obtained a substance with the composition $Mo_5O_8N_3H_3$, which they supposed to be **molybdyl triimide :**

$$Mo\begin{matrix}\diagup MoO_2.NH.MoO_2 \diagdown \\ \diagdown MoO_2.NH.MoO_2 \diagup\end{matrix}NH$$

Much heat is developed during the action, and ammonium chloride and water are formed. The compound has a black, metallic appearance, and is stable in the air; it does not combine with hydrochloric acid, but is energetically attacked by nitric acid (sp. gr. 1·42), slowly by dil. alkalis, and yields ammonia when fused with potassium hydroxide. When heated in an atm. of nitrogen, water is formed, and a red compound is obtained, which is probably molybdenum dioxide mixed with a small quantity of nitride. When treated with aq. silver nitrate, crystals of metallic silver are deposited. When molybdenyl chloride is heated to bright redness in an atm. of ammonia, an amorphous, black, metallic-looking mass is formed with the composition $Mo_7O_{14}N_5H_{10}$, **molybdyl pentamide**. It is not attacked by dil. alkalis, gives ammonia when fused with potassium hydroxide, is energetically converted into molybdic acid by the action of nitric acid, and precipitates silver from a soln. of silver nitrate. According to A. Rosenheim and H. J. Braun, when molybdenum trichloride is heated to 340° in ammonia, black **molybdenum triamidotrichloride,** $Mo_2(NH_2)_3Cl_3$, is formed—the ammonium chloride can be removed by washing with water since the amidochloride is insoluble in water and dil. acids. If kept for four days in a sealed tube with liquid ammonia, **molybdenum decamminotriamidotrichloride,** $Mo_2(NH_2)_3Cl_3(NH_3)_{10}$, it forms as a brown mass. The ammonium chloride can be removed by washing with liquid ammonia. When exposed to air, the decammine gives off ammonia, and when gently heated, it forms the triamidotrichloride. If molybdic chloride be treated with 25 per cent. aq. ammonia, the black, or dark green or brown mass has the empirical composition MoO_4NH_4, and corresponds with **molybdyl hydroxyamide,** $(NH_2)MoO_2(OH).H_2O$. H. Fleck and E. F. Smith obtained a similar product, $(NH_2)MoO_2(OH)$, by the action of dry or aq. ammonia on a chloroform soln. of molybdenyl chloride. The black precipitate—probably *molybdyl diamide,* $MoO_2(NH_2)_2$—forms the brownish-red hydroxyamide when extracted with alcohol. A. Rosenheim and F. Jacobsohn found that liquid ammonia reacts with molybdenum trioxide, forming a snow-white substance with the empirical composition $MoO_3.3NH_3$, **molybdenum triamminotrioxide,** and the same substance was formed by the action of liquid ammonia on molybdenyl chloride. The product was thought to be **ammonium imidomolybdate,** $NH:MoO(ONH_4)_2$; **ammonium lead imidomolybdate,** $(NH_4)_2Pb[Mo(NH)O_3]_2$, was also prepared. When a soln. of potassium amide in liquid ammonia acts on molybdenum trioxide, a mixture of $NH:MoO(OK)_2$, **potassium imidomolybdate,** and *potassium nitrilomolybdate* $NK:MoO(OK)_2$, appears to be formed. F. W. Bergstrom found that nitridation occurs when soln. of molybdenum halides in liquid ammonia are kept for some days. **Potassium ammoniomolybdite,** or **molybdenum amidodipotassimide,** $Mo(NK)_2NH_2$, is precipitated by adding excess of potassamide soln. to molybdenum tribromide soln., and keeping for some weeks. Free potassium is formed owing to reduction of the potassamide and " nitridation " of the molybdenum ; hydrogen and nitrogen are simultaneously formed. The compound reacts vigorously with water and is soluble in dil. sulphuric acid; it loses $0{\cdot}5NH_3$ at 120°–130° in a vacuum. The **sodium ammoniomolybdite,** or **molybdenum amidodisodimide,** is prepared using molybdenum pentachloride and sodamide.

F. Wöhler reported a **tungsten imidonitride,** $W_3N_6H_4$, or $W(NH.W.N:NH)_2$, to be formed when ammonia is passed over heated tungsten hexachloride. The black mass appears like coke. When heated in air, ammonia is first evolved, and the mass then burns to tungsten trioxide. Acids, and alkali-lye are without action; molten potassium hydroxide forms a tungstate with the evolution of ammonia and hydrogen. It is reduced to metal when heated with carbon, hydrogen and nitrogen are evolved. Ammonia is given off when the compound is heated in hydrogen, and **tungsten imide,** $W(NH.W.NH)_2$, is formed with the evolution of ammonia. At a higher temp., the metal is produced. F. W. Bergstrom observed that **potassium ammoniotungstite,** or **tungsten amidodipotassimide,** $W(NK)_2NH_2$, is precipitated as above, using a soln. of potassamide and tungsten pentabromide in liquid ammonia. It is pyrophoric, blackens in air, and reacts violently with water. If excess of halide is used in these precipitations, ammonio-basic mixtures are obtained.

S. Rideal heated tungsten trioxide with ammonium chloride until its weight was constant. The composition corresponded with *tungsten oxynitride,* $WO_3.WN_2$, or $W_2N_2O_3$. E. D. Desi reported a number of oxynitrides to be formed in an analogous manner, $W_{20}N_{27}O_4$, W_2N_4O, $W_5N_6O_4$, etc. Both A. Lottermoser, and M. Guichard consider that the alleged oxynitrides are partially reduced tungstic oxide mixed with a nitrogen compound, and possibly elemental tungsten. F. Wöhler obtained what he regarded as *tungsten oxyamidonitride,* $W_7N_8H_4O_4$, or, according to S. Rideal, $W_9N_{10}H_4O_4$, by the action of dry ammonia on heated tungsten trioxide, or an excess of ammonium chloride on potassium tungstate followed by leaching with water. The black scales give off ammonia when heated; in hydrogen, ammonia and water are given off and the metal remains; in air, tungsten trioxide is formed. The compound is also oxidized when heated with copper oxide or red-lead. With sodium hypochlorite, hydrogen is given off. Water at 230°, acids, and alkali-lye do not act on the compound, but fused potassium hydroxide forms a tungstate with the evolution of ammonia. When tungsten trioxide is heated to dull redness in a current of dry ammonia, S. Rideal said that a grey amorphous powder with the composition $W_5N_6H_3O_5$, is formed. These substances are probably mixtures.

According to E. F. Smith and O. L. Shinn, a substance with the composition $W_4N_4O_4H_2$, is formed when tungstyl chloride, WO_2Cl_2, is heated in a current of dry ammonia. There is no action at ordinary temp. The black mass is insoluble in water, it is not attacked by hydrochloric acid or dil. alkalis, but is very energetically acted on by conc. nitric acid, and yields ammonia when fused with potassium hydroxide. It is not altered by heating with conc. sulphuric acid at 180°–250°. When treated with aq. silver nitrate, crystals of metallic silver are deposited. A. Rosenheim and F. Jacobsohn said that liquid ammonia does not react with tungsten trioxide even at 108°–109° in a sealed tube; with hydrated tungsten trioxide, liquid ammonia forms **tungsten diamminotrioxide,** $WO_3.2NH_3.H_2O$; and with tungstyl chloride, brown **tungsten triamminotrioxide,** $WO_3.3NH_3$.

Uranium trioxide does not react with liquid ammonia, but uranyl chloride furnishes a greyish-green precipitate which has not been obtained pure. E. F. Smith and J. M. Matthews prepared **uranium oxynitride,** $U_{11}N_5O_{25}$, by heating uranyl chloride in a porcelain boat heated in a current of dry ammonia, when, at a comparatively low temp., the material assumes a dark colour, and copious fumes of ammonium chloride are evolved; the heat is then raised and continued until no more fumes are given off, and a dull black residue free from chlorine is left. This, when fused in a nickel crucible with potassium hydroxide, slowly evolves ammonia. When introduced into soln. of silver nitrate, brilliant crystals of metallic silver are formed. When heated in a sealed tube with dil. sulphuric acid (1–2), complete soln. ensues. V. Kohlschütter and K. A. Hofmann prepared the oxynitride, UO_5N, by dehydrating hydroxylamine uranate at 125° until the weight was constant; this is a brownish-black substance with metallic lustre; cold, dil. acids liberate a mixture of nitrogen and nitrous oxide, uranic acid remaining dissolved.

In 1894, J. Thiele and A. Lachman[10] prepared **nitramide,** or **nitroxyl amide,** $NH_2.NO_2$, *i.e.* $H_2N_2O_2$, isomeric with hyponitrous acid. They found that by adding a soln. of potassium hydroxide to a conc. aq. soln. of nitrourethane, $NO_2.NH.COOC_2H_5$, at 0°, potassium nitrocarbamate, $NO_2.NH.COOK$, separates in plates which are immediately decomposed by water with the development of heat yielding nitrous oxide and potassium carbonate; if, however, the potassium nitrocarbamate be treated with a mixture of ice and sulphuric acid, nitrocarbamic acid, $NO_2.NH.COOH$, is set free, and this at once splits up into carbon dioxide and nitramide, $NH_2.NO_2$. To isolate the nitrocarbamide, the soln. is sat. with ammonium sulphate, and extracted with ether; on evaporating the ether in a current of air at ordinary temp., the nitramide separates out in prismatic crystals, and if light petroleum be present in the ethereal soln., lustrous plates are formed. J. Thiele and A. Lachman also made it in small quantities by the action of potassium imidosulphonate in conc. sulphuric acid, on nitric acid or ethyl nitrate. Nitramide melts at 72°, but the m.p. is considerably lowered by traces of moisture. Nitramide is somewhat volatile at the ordinary temp., and dissolves in all the common solvents with the exception of light petroleum, the aqueous soln. having a strongly acid reaction. It is most unstable, and when mixed with copper oxide, lead chromate, or even glass powder, decomposes into nitrous oxide and water with development of heat. It is also decomposed by conc. sulphuric acid and by hot water, but, unlike the alkylnitramines, is equally unstable in alkaline soln. According to J. N. Brönsted and C. V. King, the decomposition of nitramide, $H_2N_2O_2 \rightarrow H_2O+N_2O$, is strongly catalyzed by platinum black, but not by bright platinum. The decomposition in water at 15° is 10 per cent. faster than the spontaneous decomposition in acid soln. at the same temp. The dissociation constant $K=2{\cdot}5\times10^{-7}$. On reduction, it yields a substance having strong reducing properties, probably hydrazine. E. Baur found the mol. conductivity, μ, of nitramide for a mol made up to 1·941 and 63·105 litres, to be between 0·5205 and 1·126; and, owing to decomposition, A. Hantzsch and L. Kaufmann found the latter value fell to 1·042. They also found for $v=32$ and 64, respectively $\mu=1{\cdot}95$ and 1·69, and consider nitramide to be an acid with a conductivity about 500 times smaller than that of acetic acid; E. Baur's results led him to conclude that the acid is 5–6 times weaker than acetic acid. A. Hantzsch measured the transport numbers of the ions, and concluded the strength of the acid is 40–50 times less than that of acetic acid. The salts are particularly unstable. J. N. Brönsted and co-workers found that the aq. soln. decomposes quantitatively: $H_2N_2O_2=H_2O+N_2O$; and is slow enough for measurement in dil. hydrochloric acid soln. at 15°. The reaction is accelerated in the presence of basic substances. J. Thiele and A. Lachman said that the *alkali nitramidates* can exist only for a few seconds; and the ethereal soln. of nitramide and an alcoholic soln. of ammonia furnish *ammonium nitramidate* which begins to give off gas immediately. J. Thiele and A. Lachman found *mercuric nitramidate*, $HgN.NO_2$, to be a little more stable. J. Thiele considered nitramide to be the true amide of nitric acid, and explained the formation of salts by the assumption that nitramide passes into the tautomeric *imidonitrous acid*, HN : NO.OH; on the other hand, A. Hantzsch did not accept the amide theory, but regarded nitramide as an acid *syn*diazohydrate, in contradistinction to the isomeric hyponitrous acid (*q.v.*) was considered to be *anti*diazohydrate.

Hyponitrous acid.

The phosphorus nitride of the early workers—H. Rose,[11] and F. Wöhler and J. von Liebig—was probably **phosphorus imidonitride,** PN_2H, or $N \vdots P : NH$, sometimes called **phospham.** It was made by F. Wöhler and J. von Liebig, C. Gerhardt, and H. Davy by heating phosphorus pentachloride in ammonia; and by H. Rose, by the action of ammonia on phosphorus pentachloride, trichloride, or tribromide: $5PCl_5+8NH_3=4PN_2H+17HCl+3H+P$. A. Besson made it by slowly heating phosphorus octamminopentachloride to 200°, and then finishing at 250°–300°; W. Couldridge, by the action of ammonia on phosphorus trinitrilohexachloride,

$P_3N_3Cl_6+3NH_3=P_3N_3(NH)_3+6HCl$; and R. Vidal, as a 90 per cent. yield, by heating a mixture of phosphorus pentasulphide and ammonium chloride. Phospham is a white, pulverulent solid. The analyses of C. Gerhardt, H. Rose, F. Wöhler and J. von Liebig, and A. Besson agree with the formula PN_2H; but the phospham prepared by A. Pauli, by the action of ammonium chloride on phosphorus pentasulphide or pentachloride, was probably impure; and the same remark applies to that prepared by M. Salzmann, by the action of ammonia on phosphorus pentachloride. Phospham can be regarded as a nitrile of phosphoric acid, H_3PO_4, formed by the abstraction of the equivalent of four mols of water from a mol of diammonium hydrogen phosphate, $(NH_4O)_2PO.OH$; phosphoryl nitrile, PON, may be regarded as derived from ammonium dihydrogen phosphate, $(NH_4O)PO(OH)_2$, by the abstraction of three mols of water; and a third nitrile would be formed by the abstraction of four mols of water from normal ammonium phosphate, $(NH_4O)_3PO$. This would furnish PN_3H_4, a compound which has not yet been reported. D. I. Mendeléeff regards phospham as a polymeride of PN_2H, analogous with hydrazoic acid or azoimide, N_3H, in agreement with the fact that both phosphorus and its compounds show a greater tendency to polymerization than nitrogen and its compounds. According to A. W. Hofmann, the non-volatility of phospham shows that it is a polymeride, probably $P_3N_3(NH)_3$, and this is in agreement with W. Couldridge's work—*vide supra.*

A. Besson found that the amide gives off ammonia when heated, and at a red-heat in vacuo, or in a stream of nitrogen, it forms phosphorus. Phospham, according to H. Rose, does not melt or volatilize, in a closed vessel protected from air, at a dull red-heat, but when heated in *air*, it forms white clouds of phosphorus pentoxide, and oxidizes slowly without inflammation. When heated in *hydrogen* it forms phosphorus and ammonia. C. Gerhardt heated phospham moistened with *water*, and found that it decomposes: $PN_2H+3H_2O=HPO_3+2NH_3$. H. Rose observed that it is not decomposed by dry *chlorine*, or dry hydrogen chloride; if moisture be present, ammonium chloride is formed. It is not dissolved or decomposed by dil. *hydrochloric acid.* F. Wöhler and J. von Liebig said that a mixture of phospham and *potassium chlorate* detonates when heated giving off chlorine. H. Rose observed that it is not decomposed in contact with molten or distilling *sulphur.* At a red-heat, dry *hydrogen sulphide* decomposes phospham, forming white clouds which condense to a white or yellowish-white powder.

This powder takes fire in air at a summer's heat, and burns with a white flame to form phosphoric acid; it is violently oxidized and dissolved by nitric acid, forming sulphuric and phosphoric acids; it inflames in the vapours of nitrogen peroxide; it has no odour when freshly prepared, but after exposure to air, it acquires the smell of hydrogen sulphide; it forms a turbid soln. when treated with water, which deposits sulphur and smells of hydrogen sulphide; it evolves ammonia when treated with alkali-lye; and it is dissolved by hot alkali-lye but not by aq. ammonia or hydrochloric acid. The product is probably a mixture of phosphorus sulphide, and ammonium salts.

Returning to phospham, H. Rose found that it is not dissolved or decomposed by dil. *sulphuric acid,* but it is dissolved by the conc. acid giving off sulphur dioxide and forming phosphoric acid. Phospham is not decomposed by dry *ammonia.* It is scarcely affected by dil. *nitric acid,* but the conc. acid slowly oxidizes it to phosphoric acid; and, added A. Pauli, it is not dissolved by fuming nitric acid. H. Rose found that a mixture of phospham and a *nitrate* detonates when heated. Phospham is not decomposed by dry *carbon dioxide,* and when heated with *alkali carbonates* it gives off carbon dioxide and ammonia, forming alkali phosphates —R. Vidal said that at a red-heat, cyanates are formed: $PN_2H+2M_2CO_3=M_2HPO_4+2MOCN$; and with *oxalates:* $PN_2H+M_2C_2O_4=M_2HPO_4+C_2N_2$. The vapour of *methyl* or *ethyl alcohol* at 150°–200° forms a phosphate of the primary amine: $PN_2H+4ROH=PO_4H(NH_2R_2)_2$ or $PO_4H(NH_2R_2)_2=ROH+R(NH_3)PO_3+NHR_2$; *propyl alcohol* gives propylamine and propyl oxide; *phenol,* diphenyl amine; *glycol* at 210° reacts: $2C_2H_4(OH)_2+PN_2H=(NH_4)_2HPO_4$

$+2C_2H_2$; *formic acid* at 150°–200° reacts: $PN_2H+2HCOOH=H_3PO_4+2HCN$; with the homologous *fatty acids*: $PN_2H+2RCOOH=H_3PO_4+2RCN$; and dioxy-compounds give diphenylamine derivatives. H. Rose found that phospham is decomposed by fused *potassium hydroxide* frequently with incandescence, forming nitrogen, hydrogen, ammonia, and alkali phosphate. Fused barium hydroxide acts similarly. Boiling alkali-lye does not decompose or dissolve phospham. F. Wöhler and J. von Liebig found that *mercuric oxide* decomposes phospham with incandescence, forming mercuric phosphate; *cupric oxide* acts similarly. F. W. Dafert and A. Uhl heated phospham with various oxidizing agents—*barium dioxide, lead chromate, lead dioxide, manganese dioxide, potassium permanganate, cupric oxide,* etc.—and found that *silver oxide* gave the most uniform results and also acted at a comparatively low temp. In these circumstances, exactly one-half of the nitrogen contained in phospham is eliminated in the form of nitrogen compounds, whilst the other half is evolved in the elementary condition. This is probably accounted for by the difference in the mode of linking of the nitrogen atoms in the phospham mol., $N \vdots P : NH$. Phospham is not greatly changed in the soil, and cannot serve as a source of nitrogen or phosphorus for plants.

The observations of G. Perpérot[12] indicate that when the ammine $PCl_3.6NH_3$ is heated, ammonium chloride and **phosphorus triamide,** $P(NH_2)_3$, are formed; and with the ammine, $PCl_5.10NH_3$, **phosphorus pentamide,** $P(NH_2)_5$. H. Perpérot represented the reaction with the phosphorus amminochlorides: $PCl_n+2nNH_3 \rightarrow PCl_n.2nNH_3 \rightarrow P(NH_2)_n+nNH_4Cl$. According to C. Hugot, liquid ammonia reacts with phosphorus tribromide a little below —70°, forming **phosphorus amide,** $P(NH_2)_3$, thus: $PBr_3+15NH_3=3NH_4(NH_3)_3Br+P(NH_2)_3$; most of the ammonium bromide can be removed by rapidly washing with liquid ammonia. If phosphorus triiodide be employed at about —65°, the amide, being soluble in the ammonium triamminoiodide, cannot be isolated. The yellow, amorphous amide is insoluble in a soln. of ammonium triamminobromide, but is soluble in the triamminoiodide; it slowly decomposes at 0° into brown **phosphorus imide,** $P_2(NH)_3$, thus, $2P(NH_2)_3=3NH_3+P_2(NH)_3$. J. A. Joannis obtained the imide by keeping the imidoamide between 0° and 100° for a few hours: $2NHPNH_2=NH_3+P_2(NH)_3$. C. Hugot observed that the soln. of the amide in ammonium triamminoiodide at —65° slowly deposits the imide. The brown imide slowly decomposes when heated; and this occurs rapidly in vacuo at 250°–300°, forming a red substance which does not decompose completely into nitrogen and phosphorus at a red-heat. The imide is insoluble in a soln. of ammonium triamminoiodide. According to R. Schenck, and A. Stock, **phosphorus imidoamide,** $H_2N.P : NH$, is probably formed as a by-product in the action of liquid ammonia on ordinary phosphorus. Yellow phosphorus, purified by distillation in a current of steam, is treated with liquid ammonia, gives off some hydrogen, and is converted into red phosphorus and small quantities of a hydride; an amide, imide, or probably phosphorus imidoamide, $NH_2.P : NH$, is formed at the same time. The hydride is said to unite with ammonia, forming a black mass which has the composition $(NH_4)P_4H$; and the reaction is accordingly symbolized: $14P+7NH_3=3P_4H(NH_4)+2NH_2PNH$. J. A. Joannis made it by passing dry hydrogen and phosphorus chloride vapour at liquid ammonia at —78°. The constancy of the proportions of imide: amide made it appear as if there was a complex formed, and at —23°, the reaction is represented: $PCl_3+14NH_3=3NH_4(NH_3)_3Cl+NH_2.P : NH$. It decomposes into the imide between 0° and 100°. Both the amide and imide have been used in the manufacture of incandescent lamp filaments by the Zirkon Glühlampenwerke.

By treating arsenic trichloride with ammonia, J. Persoz[13] obtained what he regarded as $AsCl_3.3NH_3$; H. Rose, $2AsCl_3.7NH_3$; and A. Besson, $AsCl_3.4NH_3$. The product is a pale yellow or white powder which, according to H. Rose, dissolves gradually in water with the evolution of heat, the loss of ammonia, and the formation of ammonium chloride; only a portion of the ammonia in the soln. is precipitated by hydrochloroplatinic acid. According to L. Pasteur, when heated, the product evolves ammonia, a portion then sublimes unchanged, and lastly, a sublimate of ammonium chloride is produced. When the soln. in cold water is evaporated, a substance, $As_4N_2Cl_2H_{10}O_7$, remains. This is probably a mixture of ammonium chloride, etc. Hot water decomposes the amminochloride into arsenic trioxide, ammonia, and ammonium chloride. According to J. von Liebig and F. Wöhler, the soln. formed with boiling alcohol deposits cubic crystals during the cooling. Sulphuric acid extracts ammonia from the amminochloride, and gives off arsenic trichloride. L. Pasteur found that ammonia converts the compound into ammonium arsenite. L. Pasteur regarded the product of the action of ammonia on arsenic trichloride as a mixture of ammonia, ammonium chloride, and *arsenic chloroimide*, $2As(NH)Cl+4NH_4Cl+NH_3$. According to C. Hugot, the product of the action of arsenic trichloride and ammonia is always a mixture of ammonium chloride and **arsenic amide,** $As(NH_2)_3$. He also found that between —30° and —40°, ammonia reacts with arsenious chloride, bromide, or iodide, forming arsenic amide together with the corresponding ammonium halide: $AsCl_3+6NH_3=3NH_4Cl+As(NH_2)_3$. Arsenamide is a greyish-white powder, insoluble in liquid ammonia, and stable below 0°, if kept out of contact with moist air; above 0°, it decomposes into **arsenic imide,** $As_2(NH)_3$, and ammonia: $2As(NH_2)_3=3NH_3+As_2(NH)_3$. The decomposition is complete at 60°, and the resulting imide is a stable yellow powder not decomposed in vacuo at 100°, but at 250°, it forms *arsenic nitride*, AsN, and ammonia: $As_2(NH)_3=NH_3+2AsN$, an orange-red powder which, on further heating, decomposes into arsenic and nitrogen. Water decomposes both the amide and the imide into ammonia and arsenic trioxide. According to A. Besson and G. Rosset, when arsenic tetramminotrichloride, prepared at —20°, is treated with liquid ammonia, it loses its colour, and remains colourless when the excess of ammonia is driven off. When extracted with liquid ammonia, ammonium chloride is removed and a white, insoluble residue obtained, the composition of which agrees with that of the imide, $As_2(NH)_3$. Hence liquid ammonia acts chemically on the tetrammine, and not merely as a solvent. Arsenic trichloride also reacts with $AsCl_3,4NH_3$, giving rise to ammonium chloride and a substance or mixture of substances, the composition of which is indicated approximately by the formula $As_4Cl_5N_2H_4$. E. C. Franklin found that when soln. of antimony iodide and potassium amide in liquid ammonia are mixed, an impure *antimony nitride* is formed. A. C. Vournazos[14] prepared a series of **bismuth amines** by direct combination of a tervalent bismuth salt with an inorganic or organic ammonium salt, with salts of primary or secondary amines, either aromatic or aliphatic, and with salts of primary hydrazines. Halides of bismuth yield the most characteristic compounds, but they are also given by the trioxide, nitrate, and phosphate. The bismuthamines are of two kinds, simple, in which the bismuth salt and the amine salt are derived from the same acid and mixed, in which derivatives of different acids unite. As most bismuth salts are easily hydrolyzed, bismuthamines can only be prepared in organic solvents, and from these they separate in crystalline form. The synthesis is best carried out in glacial acetic acid, by adding the bismuth salt as a dry powder or in hot acetic acid soln. to a soln. of salt of the nitrogen compound also in hot acetic acid soln. The product is filtered off. Water or alcohol decomposes the amine; and it is also decomposed by heating it to 400°. *Methylene nitratobismuthate,* $[Bi(NO_3)_4]NH_3(CH)$; and *ammonium iodotrichlorobismuthate,* $NH[BiCl_3I]$, are examples. The compounds do not give the ordinary reactions of bismuth.

F. W. Bergstrom[15] obtained **potassium manganese diamminoamide,** $Mn(NHK)_2.2NH_3$, in light yellow needles, by the action of manganese on a soln. of potassium in liquid ammonia, or better by pouring a soln. of manganese thiocyanate into an excess of a soln. of potassium amide, all in liquid ammonia. The diamminoamide decomposes in vacuo above 100°–120°. By adding potassium amide to a soln. of manganese thiocyanate in liquid ammonia, light yellow **manganese amide,** $Mn(NH_2)_2$, contaminated with some potassium, was formed. It decomposes in vacuo at 140°–175°. According to G. S. Bohart, a soln. of nickel thiocyanate in liquid ammonia gives a precipitate of nickelamide when treated with an eq. amount of potassamide soln. **Nickel amide,** $Ni(NH_2)_2$, is a red, flocculent mass which reacts mildly with water, producing nickel hydroxide and ammonia. When heated at 120° in a vacuum, it yields nickel nitride, Ni_3N_2, a black, amorphous substance which reacts extremely slowly (if at all) with water and dissolves slowly in mineral acids. At 120°, it is decomposed into its constituents. Nickelamide dissolves in an excess of potassamide soln., producing a deep red soln., which deposits a red, crystalline substance, **nickel hexamminopotassamide,** or ammonio-potassium nickelamide, $Ni_2N_3K_5.6NH_3$. It reacts violently with water. Ammonium chromium thiocyanate, $NH_4Cr(SCN)_4.2NH_3$, in liquid ammonia soln., forms at least four different compounds when treated with potassamide. These compounds are, respectively, wine-red, salmon-pink, and purple flocculent precipitates, and a wine-red, crystalline substance. Their composition has not been determined. Potassium nickel cyanide, $2KCN,Ni(CN)_2$, yields three distinct compounds when treated with a soln. of potassamide in liquid ammonia. (1) With excess of the salt, a brownish-red, slightly soluble, crystalline substance is obtained, which has the formula $Ni_3N_2H_2K_4(CN)_6,8NH_3$; when these crystals are kept at ordinary temp. and press., eight mols. of ammonia escape, and a straw-yellow powder, $Ni_3N_2H_2K_4(CN)_6$, remains. (2) With eq. amounts of salt and ammono-base, a lemon-yellow, curdy precipitate is formed; this, when washed with liquid ammonia, crumbles to a heavy powder, having the composition $K(CN)_2Ni.NHK$. (3) With a large excess of potassamide, a deep red soln. is produced, which after twelve hours, deposits deep red crystals of the compound $Ni_3N_{11}H_{22}K_7(CN)_2$.

F. W. Bergstrom[16] obtained **cobaltous amide,** $Co(NH_2)_2$, by the action of cobaltous thiocyanate on potassamide in liquid ammonia. The compound loses ammonia at 120°, forming cobaltous nitride. In 1898, A. Werner and A. Baselli discovered a complex series of cobalt ammines containing an imido-group, the **cobaltic imidoctammines.** G. Vortmann prepared what he called the *fusco-salts* by the oxidation of ammoniacal soln. of cobalt nitrate; and analogous salts were made by S. M. Jörgensen, and E. Frémy. A. Werner and F. Beddow showed that G. Vortmann's salt is really a mixture of dicobaltic oxodiimidoctamminosulphate, and dicobaltic hydrosulphatoimidoctamminosulphate. They prepared G. Vortmann's fuscosulphate as follows:

Cobalt nitrate (150 grams) dissolved in water (50 grams) is mixed with ammonia (500 grams), the soln. gradually heated to boiling and at once filtered; the filtrate is divided into 10 parts, which are placed in flasks and treated with a slow current of air as long as cobalt oxynitrate is precipitated; the dark brown soln. is allowed to remain 12 hours, and then filtered and acidified with dil. sulphuric acid. After a few hours, the precipitate of fusco-sulphate and aquopentammine sulphate is separated by filtration and washed with water until all the aquopentammine sulphate is removed. 200 grams of cobalt nitrate yield 7–7·5 grams of fusco sulphate. The yield, however, varies considerably in each experiment.

A. Werner and A. Baselli, and A. Werner and F. Beddow made **cobaltic imidoctamminotetranitrate,** $Co_2(NH)(NH_3)_8(NO_3)_4.H_2O$; **cobaltic imidoctamminodisulphate.** $Co_2(NH)(NH_3)_8(SO_4)_2.3H_2O$; **cobaltic imidoctamminotetrachloride,** $Co_2(NH)(NH_3)_8Cl_4.5H_2O$; and **cobaltic imidoctamminotetrabromide,** $Co_2(NH)(NH_3)_8Br_4.5H_2O$. They also made dihydrated and hexahydrated **cobaltic oxobisimidobisoctamminooctonitrate,** $O\{Co_2(NH)(NH_3)_8\}_2(NO_3)_8$; **cobaltic oxobisimidobisoctamminotetrasulphate,** $O\{Co_2(NH)(NH_3)_8\}_2(SO_4)_4.6H_2O$; **cobaltic oxobisimidobisoctamminoctochloride,** $O\{Co_2(NH)(NH_3)_8\}_2Cl_8.6H_2O$; and **cobaltic oxobisimidoctamminoctabromide,** $O\{Co_2(NH)(NH_3)_8\}_2Br_3.6H_2O$. They also prepared the series **cobaltic hydronitritoimidoctamminotetranitrate,** $\{Co_2(NH)(NH_3)_8(HNO_2)\}(NO_3)_4.H_2O$; **cobaltic hydronitritoimidoctamminodisulphate,** $\{Co_2(NH)(NH_3)_8(HNO_2)\}(SO_4)_2.H_2O$; and **cobaltic hydronitritoimidoctamminotetrachloride,** $\{Co_2(NH)(NH_3)_8(HNO_2)\}Cl_4.H_2O$. A. Werner, F. Steinitzer, and K. Rücker prepared **cobaltic sulphatoimidoctamminodinitrate,** $\{Co_2(NH)(NH_3)_8(SO_4)\}(NO_3)_2.3H_2O$; and **cobaltic sulphatoimidoctamminodichloride,** $\{Co_2(NH)(NH_3)_8(SO_4)\}Cl_2.3H_2O$. A. Werner and A. Baselli obtained the series **cobaltic hydrosulphatoimidoctamminotrinitrate,** $\{Co_2(NH)(NH_3)_8(HSO_4)\}(NO_3)_3$; **cobaltic hydrosulphatoimidoctamminohydrodisulphate,** $\{Co_2(NH)(NH_3)_8(HSO_4)\}(SO_4)_2H.H_2O$; **cobaltic hydrosulphatoimidoctamminotrichloride,** $\{Co_2(NH)(NH_3)_8(HSO_4)\}Cl_3.2H_2O$; **cobaltic hydrosulphatoimidoctamminodichloronitrate,** $\{Co(NH)(NH_3)_8(HSO_4)\}Cl_2(NO_3)$; **cobaltic hydro-**

sulphatoimidoctamminotribromide, $\{Co_2(NH)(NH_3)_8(HSO_4)\}Br_3.H_2O$; and **cobaltic hydrosulphatoimidoctamminotriiodide**, $\{Co_2(NH)(NH_3)_8(HSO_4)\}I_3$. A. Werner and F. Steinitzer, and A. Werner and A. Mylius prepared a series of salts whose existence had been previously established by F. Rose, and G. Vortmann, and which have been called *melano-salts* : **cobaltic imidohexamminotetranitrate**, $NH\{Co(NH_3)_4(NO_3)_2\}_2.4H_2O$, or $[NH\{CO(NH_3)_3(H_2O)_2\}_2](NO_3)_4$; **cobaltic imidohexamminotetrachloride**, $NH\{Co(NH_3)_3Cl_2\}_2$-HCl ; **cobaltic imidohexamminotetrabromide**, $NH\{Co(NH_3)_3Br_2\}_2$; and **cobaltic imidohexamminotetraiodide**, $NH\{Co(NH_3)_3I_2\}_2$. A. Werner, F. Steinitzer, and K. Rücker prepared **cobaltic ozoimidohexamminotrinitrate**, $[Co_2(O_2)(NH)(NH_3)_6(H_2O)_2](NO_3)_3$ or $Co_2(O_2)(NH)$-$(NH_3)_6(NO_3)_3.2H_2O$; and **cobaltic ozoimidohexamminohydrotrichloride**, $Co_2(O_2)(NH)$-$(NH_3)_6Cl_3.HCl$. A. Werner and F. Steinitzer made **cobaltic hydronitritoimidohexamminotetrachloride**, $\{Co_2(NH)(NH_3)_6(HNO_2)\}Cl_4.H_2O$. A. Werner, F. Steinitzer, and K. Rücker prepared **cobaltic nitratoimidotriaquohexamminotrinitrate**, $[Co_2(NH)(NH_3)_6(H_2O)_3(NO_3)](NO_3)_3$; and **cobaltic nitratoimidotriaquohexamminotrichloride**, $[Co_2(NH)(NH_3)_6(H_2O)_3(NO_3)]Cl_3$. They also prepared the series **cobaltic diozotriimidodecamminonitrate**, $Co_4(O_2)_2(NH)_3$-$(NH_8)_{10}(NO_3)_3.5H_2O$; **cobaltic diozotriimidodecamminoctochloride**, $Co_4(O_2)_2(NH)_3(NH_3)_{10}Cl_8$.$2H_2O$; and **cobaltic diozotriimidodecamminoctobromide**, $Co_4(O_2)_2(NH)_3(NH_3)_{10}Br_8.H_2O$.

§ 22. Analogies between Liquid Ammonia and Water

In its general chemical and physical properties, ammonia shows a striking resemblance to water.—E. C. FRANKLIN.

E. C. Franklin and co-workers have emphasized and developed many striking analogies between water and liquid ammonia. Among the well-known solvents, water is characterized by its high boiling point, high specific heat, high heat of vaporization, and fusion, high critical temp. and press., high association factor, and low boiling constant; by its power of uniting with salts as water of crystallization; and, excepting hydrogen cyanide, it is the most powerful ionizing solvent known—and soln. of salts are good conductors of electricity. Ammonia comes next to water in those qualities which give to the latter its unique position among solvents; its boiling point is perhaps low, but it is high in comparison with liquid methane, ethylene, hydrogen sulphide, phosphine, hydrogen chloride, etc. The specific heat of the liquid and the heat of fusion of the solid are greater than those of water; its heat of vaporization, and its critical temp. and press., are high. Ammonia is an associated liquid, and its boiling constant (3·4) is the lowest of any known liquid. It rivals water in its power to unite with salts as ammonia of crystallization; and as a solvent it is scarcely inferior to water, it can readily dissolve some salts which are but slightly affected by water—silver iodide, for instance—and its solvent action on organic compounds exceeds that of water. Ammonia is also an ionizing solvent, indeed, dil. ammonia soln. are even better conductors than dil. aq. soln.

Solvent action.—A great number of organic and inorganic compounds dissolve in ammonia—*e.g.* nitrates, nitrites, cyanides, etc.—*vide supra.* The solubility of the halogen salts in ammonia decreases with increasing at. wt. of the halogen so that the iodides are usually easily soluble, while the bromides and chlorides are but sparingly soluble, and the fluorides almost insoluble; the sulphates, sulphites, and carbonates, phosphates, arsenates, and oxalates, and the hydroxides of the alkalies and alkaline earths are usually sparingly soluble in liquid ammonia, while most are fairly soluble in water. The alkaline earth sulphides and chlorides are precipitated in liquid ammonia. The facility with which ammonia dissolves many organic compounds recalls the properties of alcohol rather than water. Determinations of the lowering of the f.p. and the raising of the b.p. of soln. in ammonia show that compounds have a great tendency to associate or to unite with the solvent.

Chemical reactions in liquid ammonia.—Reactions involving double decomposition takes place in liquid ammonia like they do in water; the reactions are of course modified by the difference in the solubilities of the reacting components in the two solvents so that reactions may take place in the one which do not occur in the other; or the direction of the reaction may be reversed. Thus, sulphides of the alkaline earths separate as white precipitates when soln. of the salts in liquid ammonia are treated with ammonium sulphide; and calcium chloride is precipitated on mixing soln. of sodium chloride and calcium nitrate in liquid ammonia. Reactions between acids and bases are limited by the insolubility of the metallic oxides and hydroxides. Many acids in the form of their ammonium salts dissolve in liquid ammonia and as such exhibit acid properties: (*a*) they discharge the red colour of phenolphthalein produced by the addition of a small quantity of liquid ammonia; (*b*) they dissolve metals like potassium, sodium, calcium, and magnesium with the evolution of hydrogen: $2M+2NH_4X=2MX+2NH_3+H_2$; and (*c*) many oxides and basic salts insoluble in ammonia dissolve in soln. of ammonium salts in liquid ammonia, *e.g.*, sodium and potassium hydroxides, and the oxides of calcium, copper, lead, magnesium, mercury, cadmium, and zinc are soluble in a soln. of ammonium nitrate in liquid ammonia, in a manner analogous to the soln. of the insoluble bases in aq. soln. of the acids: $NaOH+NH_4Cl=NaCl+H_2O+NH_3$; $CaO+2NH_4NO_3=Ca(NO_3)_2+H_2O+2NH_3$. Even in aq. soln. the acid properties of the ammonium salts are sometimes in evidence, witness the soln. of magnesium and mercury hydroxides in soln. of the ammonium salts.

Hydrates and ammoniates.—Judging from records of salts with water of crystallization and also with ammonia of crystallization, ammonia, in its tendency to unite with other compounds, probably exceeds water. Just as a salt may unite with water to form a hydrate, so can salts combine with ammonia to form ammoniates, or ammines, *e.g.* cupric and mercuric chlorides form respectively $CuCl_2.2NH_3$ and $HgCl_2.2NH_3$, etc.

Hydrolysis and ammonolysis.—The hydrolysis of salts has previously been described. Bismuth chloride hydrolyzes in a series of stages which can be symbolized:

$$\mathrm{Cl{-}Bi}<\!\begin{smallmatrix}\mathrm{Cl}\\ \mathrm{Cl}\end{smallmatrix}\rightarrow\mathrm{Cl{-}Bi}<\!\begin{smallmatrix}\mathrm{OH}\\ \mathrm{Cl}\end{smallmatrix}\rightarrow\mathrm{Cl{-}Bi}<\!\begin{smallmatrix}\mathrm{OH}\\ \mathrm{OH}\end{smallmatrix}\rightarrow\mathrm{Cl{-}Bi{=}O}$$

The corresponding action with liquid ammonia as solvent is termed ammonolysis. *E.g.*:

$$\mathrm{Hg}<\!\begin{smallmatrix}\mathrm{Cl}\\ \mathrm{Cl}\end{smallmatrix}\rightarrow\mathrm{Hg}<\!\begin{smallmatrix}\mathrm{NH_2}\\ \mathrm{Cl}\end{smallmatrix}\rightarrow\mathrm{Hg}<\!\begin{smallmatrix}\mathrm{NH_2}\\ \mathrm{NH_2}\end{smallmatrix}\rightarrow\mathrm{Hg{=}NH}$$

When aq. ammonia acts upon mercurous chloride the latter is oxidized to white amidomercuric chloride, $H_2N.HgCl$, and metallic mercury. In symbols:

$$\begin{matrix}\mathrm{Hg{-}Cl}\\ \mathrm{Hg{-}Cl}\end{matrix}+NH_3\rightarrow Hg+\mathrm{Hg}<\!\begin{smallmatrix}\mathrm{Cl}\\ \mathrm{NH_2}\end{smallmatrix}+HCl$$

The jet black colour is produced by the admixture of the finely divided mercury with the white precipitate. With aq. ammonia both hydrolysis and ammonolysis may occur, thus, with mercuric chloride:

$$\mathrm{Hg}<\!\begin{smallmatrix}\mathrm{Cl}\\ \mathrm{Cl}\end{smallmatrix}+\begin{matrix}\mathrm{H{-}OH}\\ \mathrm{H{-}NH_2}\end{matrix}\rightarrow\mathrm{Hg}<\!\begin{smallmatrix}\mathrm{OH}\\ \mathrm{NH_2}\end{smallmatrix}+2HCl$$

The so-called Millon's base, $(HgOH)_2NH_2OH$, is formed as a yellow precipitate when mercuric oxide is boiled with aq. ammonia: $2HgO+NH_4OH\rightleftharpoons(HgOH)_2NH_2OH$; and the precipitate formed when Nessler's reagent reacts with an ammonium salt is to be regarded as an iodide of Millon's base—mercuric ammonohydroxyiodide, that is dimercurihydroxyammonium iodide, $HO-Hg-NH-Hg-I$. The following are typical ammonolytic reactions:

$$SiCl_4+8NH_3\rightleftharpoons Si(NH_2)_4+4NH_4Cl; \qquad 3TeCl_4+16NH_3\rightleftharpoons Te_3N_4+12NH_4Cl$$
$$BCl_3+6NH_3\rightleftharpoons B(NH_2)_3+3NH_4Cl; \qquad PC_3+5NH_3\rightleftharpoons P(NH)NH_2+3NH_4Cl$$

Just as some hydrolytic reactions proceed to completion, others are reversible, so with ammonolytic reactions, some proceed energetically to the end, while others are balanced against a counter-reaction, *e.g.* $HgCl_2+2NH_3\rightleftharpoons NH_2HgCl+NH_4Cl$; and $2HgI_2+4NH_3\rightleftharpoons HgNHgI+3NH_4I$. The following reactions which proceed in aq. soln. resemble the corresponding reactions in liquid ammonia:

$$2AgNO_3+2KOH\rightleftharpoons Ag_2O+2KNO_3+H_2O; \qquad AgNO_3+KNH_2\rightleftharpoons AgNH_2+KNO_3$$
$$HgCl_2+2KOH\rightleftharpoons HgO+2KCl+H_2O; \qquad 3HgI_2+6KNH_2\rightleftharpoons Hg_3N_2+6KI+4NH_3$$
$$2BiCl_3+6KOH\rightleftharpoons Bi_2O_3+6KCl+3H_2O; \qquad BiBr_3+3KNH_2\rightleftharpoons BiN+3KBr+2NH_3$$

Just as with potassium hydroxide in aqueous solutions, sometimes the hydroxide and sometimes the oxide is formed, so in ammonia solutions, potassium amide furnishes the amide, the imide, or the nitride.

Acids, bases, and salts.—To distinguish between the ordinary oxygen salts, acids, and bases and those compounds which bear an analogous relation to ammonia, E. C. Franklin applies the term *hydro-salts*, *hydro-acids*, and *hydro-bases* to those compounds which are related to water, like the *ammono-salts*, *ammono-acids*, and *ammono-bases* are related to the corresponding ammonia derivative. The terms *aquo-salts*, *aquo-acids*, and *aquo-bases* are similarly applied—*e.g.* potassium nitrate is an aquo-salt; potassium hydroxide or calcium is an aquo-base; and acetic acid is an aquo-acid, while potassium acetamide, $CH_3.CO.NHK$, or $CH_3.CO.NK_2$, is an ammono-salt; sodium amide is an ammono-base; and acetamide, $CH_3.CO.NH_2$, is an ammono-acid.

Ammono-acids.—These are represented by the acid amides, acid imides, and acid nitrides. They are soluble in liquid ammonia, and their solutions discharge the colour of alkaline soln. of phenolphthalein; they usually conduct the electric current, and react with the ammono-bases to form ammono-salts. Representatives of the ammono-acids are numerous in organic chemistry, the amides of sulphuric and nitric acids are also well-known, and generally, the amides, imides, and nitrides of the non-metallic elements. Just as the halogen derivatives of the strongly electro-negative elements—*e.g.* arsenic, phosphorus, boron, silicon, etc.—are completely hydrolyzed by water, so the same compounds in liquid ammonia are decomposed, forming compounds which bear analogous relations to the solvent ammonia, as the hydrolytic products bear to water. *E.g.* $AsCl_3+6NH_3\rightleftharpoons As(NH_2)_3+3NH_4Cl$; $SiS_2+4NH_3\rightleftharpoons Si(NH)_2+2NH_4HS$; etc.

Ammono-bases.—This class of compounds is represented by the metal amides, imides, and nitrides,. Just as the hydroxides of the alkali metals are easily soluble in water, so are the amides of the alkali metals readily soluble in liquid ammonia. The solubility of potassamide in liquid ammonia enabled E. C. Franklin to prepare a number of insoluble metal derivatives by bringing together potassamide and the metal salts in ammonia soln. Thus, potassamide reacts with silver nitrate, forming silver amide: $AgNO_3+KNH_2\rightleftharpoons AgNH_2+KNO_3$; with lead nitrate or iodide, lead imide is formed: $Pb(NO_3)_2+2KNH_2\rightleftharpoons PbNH+2KNO_3+NH_3$; and with bismuth iodide, to form bismuth nitride, $BiI_3+3KNH_2=BiN+3KI+2NH_3$. These bases are insoluble in ammonia, but readily dissolve in ammonia solutions of the ammonium salts; and they are decomposed by water with the evolution of ammonia.

Ammono-salts.—The acid and metal amides are related to ammonia much as the ordinary acids and bases are related to water. The acid amides discharge the colour from an alkaline soln. of phenolphthalein in liquid ammonia, while the soluble metal amides give the characteristic colour with the same indicator, and they react with one another in soln. in liquid ammonia, forming metal derivatives of the acid amides in a manner analogous with the interaction of acids and bases in aq. soln., forming a class of compounds related to ammonia as ordinary salts are related to water. The metal and acid amides neutralize one another and phenolphthalein can be used as indicator. Thus, with acetic acid, CH_3COOH, and potassium hydroxide in aq. soln.: $CH_3COOH+KOH\rightleftharpoons CH_3COOK+H_2O$; and acetamide, CH_3CONH_2, and potassamide, KNH_2, in soln. in liquid ammonia, react: $KNH_2+CH_3CONH_2\rightleftharpoons CH_3CONHK+NH_3$. Certain heavy metals amides form ammono-bases and ammono-basic salts by reactions analogous to the formation of insoluble bases and salts from aq. soln. Oxides and hydroxides of some metals are soluble in an excess of a strong base like potassium hydroxide to form a class of salts typified by potassium zincate: $2KOH+Zn\rightarrow Zn(OK)_2+H_2$; and certain metal amides—*e.g.* the amides of nickel, cadmium, silver, aluminium, copper, lead, etc.—are soluble in the amides of more basic elements—*e.g.* potassium amide—to form analogous ammono-salts. For instance, zinc amide or zinc iodide is acted upon by liquid ammonia solution of potassium amide in an analogous manner: $2KNH_2+Zn\rightarrow Zn(NHK)_2+H_2$, and the *potassium ammono-zincate* takes up ammonia of crystallization, forming well-defined crystals. Similarly, the reaction: $SnI_4+4KOH\rightleftharpoons Sn(OH)_4+4KI$ can be contrasted with $SnI_4+4KNH_2\rightleftharpoons Sn(NH_2)_4+4KI$; and the reaction: $Sn(OH)_4+4KOH\rightleftharpoons Sn(OK)_4+4H_2O$, can be contrasted with $Sn(NH_2)_4+4KNH_2\rightleftharpoons Sn(NHK)_4+4NH_3$. The ammonia analogue of potassium stannate is thus *potassium ammono-stannate*, $Sn(NK)_2.4NH_3$, or $Sn(NH_2)_4.2KNH_2$. The following is a selection of examples from E. C. Franklin's list in which the hydro- and ammono-acids bases and salts are compared:

WATER OR OXYGEN TYPE.		AMMONIA OR NITROGEN TYPE.	
I. *Aquo-acids and acid anhydrides.*		*Ammono-acids and acid nitrides.*	
Nitric acid	$NO_2.OH$	Nitramide	$NO_2.NH_2$
Sulphuric acid	$SO_2(OH)_2$	Sulphimide	$SO_2(NH_2)_2$
Carbonic acid	$CO(OH)_2$	Carbamide	$CO(NH_2)_2$
Orthosilicic acid	$Si(OH)_4$	Silicon amide	$Si(NH)_2$
Silicic anhydride	SiO_2	Silicon nitride	Si_3N_4
II. *Aquo-bases and basic oxides.*		*Ammono-bases and basic nitrides.*	
Lithium hydroxide	$LiOH$	Lithium amide	$LiNH_2$
Lithium oxide	Li_2O	Lithium nitride	Li_3N
Calcium hydroxide	$Ca(OH)_2$	Calcium amide	$Ca(NH_2)_3$
Mercuric oxide	HgO	Mercuric nitride	Hg_3N_2
Bismuth oxide	Bi_2O_3	Bismuth nitride	BiN
III. *Aquo-salts.*		*Ammono-salts.*	
Potassium sulphate	$SO_2(OK)_2$	Dipotassium sulphamide	$SO_2(NHK)_2$
Potassium acid sulphate	$SO_2.OH.OK$	Monopotassium sulphamide	$SO_2(NH_2)NHK$
Potassium carbonate	$CO(OK)_2$	Dipotassium urea	$CO(NHK)_2$
Potassium acid carbonate	$CO.OH.OK$	Monopotassium urea	$CO(NH_2)NHK$
Potassium acetate	$CH_3.COOK$	Potassium acetamide	$CH_3.CO.NK_2$
IV. *Amphoteric hydroxides, etc.*		*Amphoteric amides, imides, and nitrides.*	
Zinc hydroxide	$Zn(OH)_2$	Zinc amide	$Zn(NH_2)_2$
Silver hydroxide (?)	$AgOH$	Silver amide	$AgNH_2$
Lead hydroxide	$Pb(OH)_2$	Lead imide	$PbNH$
Thallium hydroxide (?)	$TlOH$	Thallium nitride	Tl_3N
Potassium stannate	$K_2SnO_3.3H_2O$	Potassium ammonostannate	$K_2Sn(NH)_3.3NH_3$
V. *Aquo-basic salts.*		*Ammono-basic salts.*

Ionization of liquid ammonia and water solutions.—Solutions of certain salts in liquid ammonia are good conductors of electricity so that liquid ammonia approaches water in its ionizing power. The effect, however, is largely due to the high speed at which the ions are supposed to travel in the solvent. For example, E. C. Franklin and H. P. Cady [1] find that univalent ions travel, at −33°, nearly three times as fast as in aq. soln. at 18°. Just as the solvent water, in the ionization theory of hydrolysis, is supposed to be ionized $H_2O=OH'+H^{\cdot}$, so in ammonolysis, the solvent ammonia is supposed to be ionized $NH_3=NH_2+H^{\cdot}$. Sodamide, $NaNH_2$, furnishes sodium ions $Na^{\cdot}$ and amide ions NH'_2 when dissolved in liquid ammonia, and it is to be considered as a base. It reddens phenolphthalein. The neutralization of this solution results in the union of $H^{\cdot}$ ions with NH_2 ions to form ammonia molecules, just as the neutralization of bases is regarded as an effect of the union of $H^{\cdot}$ and OH' ions. Acetamide, $CH_3.CO.NH_2$, ionizes in liquid ammonia in an analogous manner: $CH_3.CO.NH_2 \rightleftharpoons CH_3.CO.NH'+H^{\cdot}$, and it thus behaves as an acid.

§ 23. Hydroxylamine

Ammonia is the end-product of the reduction of nitric oxide by hydrogen: $2NO+5H_2 \rightarrow 2H_2O+2NH_3$; the reduction, however, may take place in stages: $NO \rightarrow NH_2OH \rightarrow NH_3$. When the conditions are favourable, the incompletely reduced intermediate compound may predominate among the products of the reduction. The compound, symbolized NH_2OH, is called **hydroxylamine,** because it can be regarded as water with a hydrogen atom replaced by the amine-group, NH_2. E. Wagner compared hydroxylamine with hydrogen dioxide, where one HO-group is replaced by a NH_2-group. Hydrogen dioxide is obtained by reducing oxygen; hydroxylamine, by reducing oxygen derivatives of nitrogen. Both compounds are unstable, one producing water and oxygen, the other ammonia and oxidation products. From the opposite point of view, hydroxylamine, together with *dihydroxyammonia*, $NH(OH)_2$, can be regarded as intermediate compounds in the oxidation of ammonia:

NH_3	NH_2OH	$NH(OH)_2$	$N(OH)_3$
Ammonia.	Hydroxylamine.	Dihydroxyammonia.	Orthonitrous acid.

E. Divers and T. Shimidzu believed that in the reduction of dil. nitric acid by zinc, ammonia and hydroxylamine are not consecutive products, but are produced by parallel and independent reactions. They said that when once formed, hydroxylamine is not readily reduced to ammonia, and is therefore not necessarily an intermediate stage in the reduction to ammonia. They also showed that the presence of sulphuric acid favours the formation of hydroxylamine, but no explanation of this peculiar effect has yet been made. By using a great excess of sulphuric acid they found, in accord with J. B. Kinnear's result, that nearly, if not all the nitric acid unconverted to hydroxylamine is converted into ammonia. N. R. Dhar suggested that ammonia being more basic than hydroxylamine is more difficult to form in strongly acidic soln. In opposition to O. von Dumreicher, E. Divers and T. Haga said that an acidified soln. of stannous chloride does not reduce nitric oxide to ammonia if no air (nitrogen peroxide) be present. Under these circumstances only hydroxylamine is produced. The reduction does not occur at 100°, the reduction is small at 90°, and as the temp. falls, the reaction becomes more and more pronounced. One of the old terms for hydroxylamine is *oxyammonia.* The second oxidation product, $NH(OH)_2$, has not been isolated; but in a paper *Ueber das Hydroxylamine*, 1865, W. Lossen[1] announced the discovery of hydroxylamine among the reduction products of nitric acid or nitric oxide by nascent hydrogen: $2NO+3H_2 \rightarrow 2NH_2OH$. W. Lossen's discovery of hydroxylamine not only threw much light on the nature of the reduction of nitric acid, but it also enriched chemistry with a substance which possessed interesting and useful properties. Hydroxylamine has proved of great value in studying the structure of organic compounds; it has been used in photography; as an antiseptic; as a reducing agent in analytical and synthetic chemistry; etc.

The preparation of hydroxylamine salts.—Hydroxylamine is formed by the reducing action of nascent hydrogen on nitric oxide, nitric acid, nitrous acid, certain nitrates, or nitro-bodies. For instance, W. Lossen passed a stream of nitric oxide through a soln. of tin dissolving in hydrochloric acid: $2NO+3H_2=2NH_3O$. The soln. will contain a compound of hydroxylamine and hydrogen chloride—hydroxylamine hydrochloride—and also tin chloride. The tin may be precipitated by passing hydrogen sulphide through the soln. The liquid is then filtered and evaporated to dryness. The residue is extracted with absolute alcohol, and, on evaporation, white crystals of hydroxylamine hydrochloride, $NH_2OH.HCl$, are obtained. E. Ludwig and T. Hein, and E. Divers and T. Haga, and E. Divers and T. Shimidzu used a similar process. E. Frémy reduced nitrous acid and nitrates by tin and hot conc. hydrochloric acid; E. J. Maumené, ammonium nitrate; J. Donath, sodium nitrate; and B. Lengyel, potassium nitrate. W. Lossen obtained hydroxylamine by the action of tin on nitric acid, and E. Divers showed that the presence of hydrochloric or sulphuric acid favours the reaction. L. H. Milligan and G. R. Gillette studied the reduction of free nitric acid by stannous chloride, ferrous salts, and by titanous salts—*vide infra*, nitric acid. W. Lossen, and B. Lengyel obtained the base by the action of tin and hydrochloric acid on ammonium, potassium, sodium, or ethyl nitrate ; E. Frémy, and E. Divers and T. Haga, by the action of hydrogen sulphide, sulphur dioxide, and sulphides on nitric acid ; E. Divers and T. Haga, by treating silver nitrite suspended in water, or a mixture of copper sulphate and potassium nitrite with hydrogen sulphide ; or by treating silver or mercurous nitrite with sulphurous acid ; E. Divers and T. Haga, and F. Raschig, by reducing sodium nitrite with sulphites ; A. Lidoff, by reducing nitrites, say mercury or silver nitrate, with hyposulphurous acid ; E. Divers, E. Frémy, and E. J. Maumené, by reducing, say, sodium nitrite with sodium amalgam ; and A. Jouve, by reducing nitric acid with hydrogen in the presence of spongy platinum between 115° and 120°. M. Coblens and J. K. Bernstein observed that hydroxylamine is formed when silver hyponitrite or a soln. of sodium nitrite is added drop by drop to an acid soln. of stannous chloride.

C. F. Böhringer, and J. Tafel recommended making hydroxylamine by the electrolytic reduction of nitric or nitrous acid, or the corresponding salts, in a partitioned cell containing sulphuric acid with nitric acid in the cathode compartment, and amalgamated lead electrodes. E. P. Schoch and R. H. Pritchett used as anode a lead pipe or rod about 1 inch in diameter instead of a graphite rod. The cathode compartment is filled with a mixture of three vol. water to one vol. of hydrochloric acid (sp. gr. 1·20). The anode liquid is cooled by causing it to circulate continually through a lead pipe coil immersed in the freezing mixtures used to cool the cathode liquid. The current used is 50 ampères at 25 volts, and the nitric acid (sp. gr. 1·4) mixed with one vol. of water is run into the cathode compartment at the rate of 30 c.c. per hour, the addition being allowed to proceed for two and a half hours. The cathode liquid is concentrated in vacuo on a water-bath, and the hydroxylamine chloride freed from ammonium chloride by crystallization from alcohol. G. Ponzio and A. Pichetto recommended the following method of preparation :

A convenient cell consists of a glass beaker, 8·5 cms. wide and 15 cms. high, the anode being a cylinder 4·7 cms. in internal diameter and about 110 sq. cms. in area, made of lead sheet 1·2 mm. thick, and the cathode a similar cylinder, 7 cms. in diameter, about 100 sq. cms. in area, and with 30 holes 0·5 cm. in diameter. An ordinary porous pot, 5·5 cms. wide inside and 3·5 mm. thick, served as diaphragm, and the anolyte is composed of 200 c.c. of sulphuric acid having a sp. gr. of 1·553 at 15°, and the catholyte of 150 c.c. of the same acid containing in soln. 10 g. of sodium nitrate. A current of 5 amps. is maintained by means of a potential difference of 3·7–3·6 volts between the electrodes, and the cell is kept immersed in cold water during the electrolysis. When the nitrate ions completely disappear, this occupying 2–3 hrs., further quantities of 10 g. of sodium nitrate are added, a total amount of 60 g. being employed. The current efficiency amounts to 20–22 per cent., and the yield of hydroxylamine calculated on the sodium nitrate, to 14·5–15 per cent. of the theoretical. To isolate the hydroxylamine, the neutralized cathodic liquid is heated to 70°–80° with acetone, and after 12 hrs., the separated sodium sulphate crystals are filtered off and washed with benzene, with which also the filtrate is extracted four times. The benzene soln. is shaken with 20 per cent. hydrochloric acid, the acid soln. being conc. to small volume by boiling and then evaporated to dryness on a water-bath. The hydroxylamine hydrochloride thus obtained is quite free from ammonium salts and becomes perfectly white if crystallized once from one-half its weight of water.

J. Tafel electrolyzed a soln. of 0·4 grm. of nitric acid and 20 c.c. of 50 per cent. sulphuric acid, using 10 sq. cms. of cathode surface and 2·4 amps. at 0°. The product of the reduction is largely dependent on the nature of the metal used as electrode. Some results are indicated in Table XXVII. With platinum, no ammonia or hydroxylamine was formed, and with palladium the reduction is extremely slow. The chief products of the reduction are hydroxylamine and ammonia. The largest proportion of the hydroxylamine is formed when mercury is used as cathode, and the conversion of the nitric acid into this can be carried out almost quantitatively. With lead electrodes, about 40 per cent. of the nitric acid is converted into hydroxylamine, and with copper electrodes only about 15 per cent. ; if the copper be in the form of a spongy mass, only about one per cent. of the acid is transformed into hydroxylamine, the remainder being reduced to ammonia. When an amalgamated (lead, tin, or copper) cathode is used, the reduction takes place in the same way as when a mercury cathode is employed. Hydroxylamine is not reduced when subjected to electrolysis between copper electrodes ; and the reduction of nitric acid does not, at least between copper electrodes, always go through the hydroxylamine stage.

TABLE XXVII.—THE ELECTROLYTIC REDUCTION OF NITRIC ACID.

Cathode material.	Nature of surface.	Time hrs.	Products of reduction.			
			NH_2OH	NH_3	HNO_2	Gas.
Lead . .	prepared	2·5	24·7	59·9	0·8	7·3
Lead . .	amalgamated	2·5	69·7	16·9	0·1	9·2
Tin . .	polished	3·0	43·3	40·4	0·7	7·3
Copper . .	polished	2·5	11·5	76·8	trace	7·1
Copper . .	spongy	2·5	1·3	93·0	0·1	3·4
Silver . .	polished	3·0	22·3	47·2	1·5	19·7

The amount of hydroxylamine produced is greater as the soln. of nitric acid is more dil. ; in order to obtain the largest proportion, a very dil. soln. of nitric acid should be used, and more added as the reduction proceeds. When the amount of sulphuric acid present falls below 40 per cent., the quantity of hydroxylamine formed decreases appreciably, but otherwise the conc. of the sulphuric acid exerts no influence on the reaction. In the production of hydroxylamine, the current yield is greatest for lead, slightly less for amalgamated lead, and decidedly less for copper. The presence of nitrous acid is said to exert no appreciable influence on the reduction of nitric acid at cathodes of these metals. E. Divers, and J. Tafel agree that the yield of hydroxylamine increases with increasing conc. of sulphuric or hydrochloric acid, although E. Divers observed that with the latter, the yield passes through a maximum. H. E. Patten made some observations on this subject. The relation of sulphuric acid to the yield of hydroxylamine is not known. E. Divers said that there is no reason to believe that the action of the hydrochloric or sulphuric acid upon the metal is instrumental in forming hydroxylamine. The second acid serves to decompose the metal nitrate as fast as it is produced. In this way, it holds the hydroxylamine in a state more stable than the nitrate. This agrees with the observations of O. Flaschner, that hydroxylamine lowers only slightly the decomposition voltage of $2N$-H_2SO_4 at a mercury cathode, while that of $2N$-HNO_3 is lowered nearly 0·4 volt. This means that under the given conditions nitric acid is a better oxidizing agent than hydroxylamine and will be used up before the hydroxylamine : E. J. Joss also found nitrous acid is slightly less powerful than nitric acid. E. Divers's second point, (ii) that the second acid preserves the hydroxylamine from the destructive action of the nitrous acid, by preventing the formation of this substance which would otherwise result from the reaction between the metal yielding hydroxylamine and its own nitrate. J. Tafel, however, found that this is not correct because nitrous acid has very little effect on the reduction. E. Divers's third point, (iii) that the second acid determines the reduction of all the nitric acid to hydroxylamine by supplying the hydrogen for reducing it, and so keeping it free to the last. J. Tafel, however, doubted this because in very conc. soln., the free acid or $H^{\cdot}$-ion conc. is low.

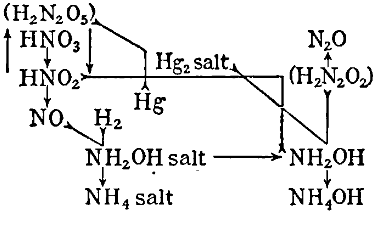
J. Tafel further showed that the production of ammonia does not always pass through the hydroxylamine stage. He said :

> Nitric acid dissolved in sulphuric acid is reduced electrolytically at an amalgamated cathode almost exclusively to hydroxylamine, although such a cathode has a distinct electrolytic reducing action on hydroxylamine sulphate. On the other hand, nitric acid is reduced almost completely to ammonia at a copper cathode which is effective only at

> low current densities and which is quite inadequate to reduce hydroxylamine sulphate any further. The only safe conclusion to draw is that the electrolytic reduction of nitric acid to ammonia at a copper cathode does not pass through the hydroxylamine stage. Certain cathode materials, such as copper, for instance, by a chemical action divert the reduction process somewhere between nitric acid and hydroxylamine from the sp. electrolytic course so that the reaction goes direct to ammonia, without passing through the hydroxylamine stage. I cannot tell certainly at what stage the switching of the reaction takes place ; but it seems not improbable that it occurs at dihydroxylamine, $NH(OH)_2$.

J. Tafel could not reduce hydroxylamine at the copper cathode, but it passes to ammonia at the amalgamated copper cathode. O. Flaschner, however, did reduce the hydroxylamine at the copper cathode, because, added J. Tafel and H. Hahl, he worked with soln. so dil. that the hydrolyzed hydroxylamine undergoes reduction, not the hydroxylamine itself. The hydrogen over-voltage at the amalgamated copper cathode is higher than it is at a copper cathode, and hence reducing effects may be possible with the former and not possible with the latter. All the amalgamated cathodes used by J. Tafel gave high yields of hydroxylamine ; this is taken to be a specific property of the mercury since no mercury ions are present. The high over-voltage of mercury might be expected to carry the reduction to the ammonia stage. He found that no hydroxylamine is produced when mercury is treated with nitric acid. It was accordingly inferred that the chemical and electrolytic processes are different. J. A. Wilkinson showed that the different results are determined by the presence of mercury ions ; if the conc. of the mercury ions be kept low, the chemical process also furnishes hydroxylamine. J. Tafel's experiments show that hydroxylamine does not depolarize the decomposition of 50 per cent. sulphuric acid at a copper cathode. E. Müller showed that there is a peculiar relation between the conc. of the acid and the depolarizing power of hydroxylamine because the oxidizing power of hydroxylamine in alkaline soln. is greater than that of either the nitrate or the nitrite ; and no appreciable yield of hydroxylamine could be obtained by the electrolysis of neutral soln.

V. Sihvonen studied the electrolysis of nitric acid with platinum or copper cathodes, with a cathode of mercury in phosphoric or sulphuric acid at 25°–40° ; and also the electrolysis of hydroxylamine with the same cathodes. His idea of the mechanism of the reactions in the two cases is illustrated by :



where the symbols of the hypothetical intermediate compounds are bracketed. The compounds following one another in the scheme are reduced in acidic soln. with increasing cathodic potential. Down to nitric oxide, the reduction proceeds without the evolution of hydrogen—*vide infra*, nitric acid.

According to E. Carstanjen and A. Ehrenberg, and A. Steiner, hydroxylamine hydrochloride is formed when mercury fulminate, $C_2N_2O_2Hg$, is treated with hydrochloric acid ; R. Preibisch obtained it by the reduction of aliphatic nitro-compounds—*e.g.* nitro-methane ; V. Meyer and J. Locher, and G. Chancel, by reducing dinitropropane, dinitrobutane, ethylnitrolic acid, and the ammonium salt of nitroform ; and J. Kachler, by reducing dinitroheptylic acid. In E. Divers and T. Haga's process hydroxylamine disulphonate, $N(HSO_3)OH$, is first prepared by the interaction of sodium nitrite and sodium sulphide, and this is subsequently decomposed by heating it with water, whereby hydroxylamine sulphate is produced. Details are as follow :

Conc. soln. of two mol. eq. of sodium nitrite and one of sodium carbonate are treated with sulphur dioxide until the mixture has an acid reaction. The sodium salt of hydroxylamine disulphuric acid, $HO.N(HSO_3)_2$, is formed, and this decomposes on the addition of a little sulphuric acid into the sodium salt of hydroxylamidosulphonic acid, $HO{\cdot}NH.HSO_3$, and sodium hydrosulphate, $NaHSO_4$. When the first-named salt has stood a couple of days at 90°–95°, it breaks down still further into hydroxylamine, $HO{\cdot}NH_2$, and sodium bisulphate. The latter is first crystallized from the soln., and crystals of hydroxylamine sulphate are subsequently separated. Potassium salts do not give so good a yield as the sodium salts. Very little ammonia is formed. W. L. Semon modified this process.

The isolation of hydroxylamine.—W. Lossen prepared an aq. soln. of the free base (i) by adding the proper amount of baryta-water to precipitate all the combined sulphuric acid as barium sulphate; and (ii) by treating a conc. aq. soln. of the sulphate or nitrate with an alcoholic soln. of potassium hydroxide, whereby potassium sulphate or nitrate is precipitated. When the attempt is made to concentrate the aq. soln. of the base by evaporation in vacuo, the soln. begins to decompose; and if the aq. soln. is distilled, a great proportion of the hydroxylamine is decomposed into ammonia, etc., and the remainder passes along with steam to the receiver.

Up to 1890, hydroxylamine was known only in the form of its salts or in aq. soln. W. Lossen tried, without success, to isolate the base by distilling the aq. soln. C. A. Lobry de Bruyn assumed that the presence of water was the secret of W. Lossen's failure to isolate the base, and he tried alcohol as solvent. Solubility of the hydroxylamine in methyl alcohol was found to be greater than in ethyl alcohol. He succeeded in isolating the base by distillation from a mixture of sodium methoxide, and hydroxylamine chloride.

To isolate hydroxylamine, dissolve the hydrochloride in methyl alcohol and add sodium methylate (obtained by dissolving metallic sodium in methyl alcohol). Filter off the sodium chloride, and remove the alcohol by distillation—at first under ordinary press. and then under reduced press. The hydroxylamine distils at about 70° under a press. of 60 mm.; or at, say, 58° under a press. of 22 mm. The method was modified a little by J. Houben, H. Lecher and J. Hofmann. A 40 per cent. yield was obtained by using absolute alcohol; and C. D. Hurd and H. J. Brownstein, obtained a 50 per cent. yield by using butyl alcohol. The explosive properties of the hydroxylamine and the precautions to be taken in its preparation were discussed by C. A. Lobry de Bruyn, J. W. Brühl, R. Uhlenhuth, and R. Wolffenstein and F. Groll. Almost at the same time as C. A. Lobry de Bruyn, L. Crismer obtained the base by passing ammonia through a mixture of ether with the complex salt zinc hydroxylamine chloride, $ZnCl_2{\cdot}2NH_2OH$; he distilled off the ether, and finally the hydroxylamine. R. Uhlenhuth isolated the base by distillation from the phosphate under diminished press. According to E. Ebler and E. Schott, the solid can be further purified by crystallization from alcohol at —18°, when conc. soln. deposit the base in white leaflets, and dil. soln. in needles. O. Baudisch and F. Jenner added finely powdered and dried hydroxylamine sulphate to liquid ammonia in a quartz tube, and removed the ammonia by evacuation; the free hydroxylamine was extracted by alcohol.

The physical properties of hydroxylamine.—Anhydrous hydroxylamine furnishes transparent plates (L. Crismer), needles (C. A. Lobry de Bruyn, and J. W. Brühl), without taste or smell. H. Lecher and J. Hofmann said that the crystals obtained from ethyl alcohol, or by the solidification of the molten substance, are identical, and belong to the rhombic system. C. A. Lobry de Bruyn gave 1·35 for the sp. gr. of the crystals at 18°; and 7·235 for the molten salt. J. W. Brühl gave 1·2255 for the sp. gr. at 0°/4°; 1·2156 at 10°/4°; and 1·2044 for the liquid at 23·5°/4°. E. Schott obtained very different values for the highly purified hydroxylamine; he gave 1·0742 at 19·1°/4°; and 1·0717 for 20°/4°. H. Lecher and J. Hofmann gave 1·335 at 10°, and 1·334 at 14°. Considering hydroxylamine as the amido-derivative of water, C. A. Lobry de Bruyn inferred that hydroxylamine would be solid at ordinary temp. because the substitution of a NH_2-group in place of hydrogen usually raises the b.p. and the m.p. The argument from analogy turned out to be correct. The crystals when first prepared melt at 33°, and after standing for some hours, they melt at 27·5°. J. W. Brühl gave 32°–33° for the freezing temp., and in a capillary tube, they fused at 33°–34°. H. Lecher and J. Hofmann gave 32°–35° for the m.p. According to C. A. Lobry de Bruyn, if the cooling liquid be at rest, it can be under-cooled down to 0°—solidification occurs instantly if the liquid be then shaken. The b.p. is 56°–57° under 22 mm. press. At ordinary press., hydroxylamine gradually decomposes if kept over 15°, and at higher temp. it is liable to explode with a yellow flash. H. Lecher and J Hofmann's preparation was less stable than that of C. A. Lobry de Bruyn, for it smelt of ammonia after keeping 24 hrs., and in 4 days it completely liquefied and contained only 42·55 per cent. of hydroxylamine. C. A. Lobry de Bruyn said that if hydroxylamine be heated slowly on platinum foil, it burns with a yellow flame ; but if a drop be heated in a test-tube over the free flame, it explodes with a loud noise. The solid decomposes on standing a short time in air. G. M. J. MacKay found the mol. depression of the f.p. to be 1·77°, 1·90° and 2·25° respectively for soln. with a mol of hydroxylamine in 1, 20, and 500 litres of soln. These results agree with the conductivity measurements in showing a slight ionization of the hydroxylamine in aq. soln. M. Berthelot and C. Matignon gave —3·8 Cals. per mol for the heat of soln. in water ; and M. Berthelot and G. André, 23·8 Cals. for the heat of formation in aq. soln.

W. N. Hartley and J. J. Dobbie examined the spectrum of hydroxylamine ; and W. B. Brodie, the spectrum of blood treated with hydroxylamine. C. A. Lobry de Bruyn reported the index of refraction at 14° to be $\mu_\alpha=1{\cdot}44123$; $\mu_\beta 1{\cdot}45025$; and $\mu_A=1{\cdot}43035$; and at 40°, $\mu_\alpha=1{\cdot}43350$; $\mu_\beta=1{\cdot}44299$; and $\mu_A=1{\cdot}42298$. J. W. Brühl gave at 23·5°, 1·43754 for the Li-ray ; 1·44323 for the Tl-ray ; 1·43801 for the H_α-ray ; 1·44652 for the H_β-ray ; 1·44047 for the Na-ray ; and 1·45137 for the H_γ-ray. This makes for the dispersion $\gamma-\alpha=0{\cdot}0057$, or $M(\gamma-\alpha)=9{\cdot}19$. E. Schott gave at 14·5°, $\mu=1{\cdot}41723$ for the H_α-line ; 1·41952 for the Na-line ; 1·42476 for the H_β-line ; and 1·42917 for the H_γ-line, giving $M(\gamma-\alpha)=8{\cdot}09$. According to E. Schott, the mol. refraction for NH_2OH is 7·257 and the dispersion 0·211 ; and for $H_3N=0$, 8·14, and 0·59.

E. C. Szarvasky found that the electrolysis of hydroxylamine was accompanied by the spontaneous transformation of hydroxylamine into ammonia. Secondary reactions always occur—the base being reduced to ammonia at the cathode and at the anode oxidized to nitrogen oxides. F. Balla found that with various electrodes the percentage current yield of $NaNO_2 : NaNO_3$ in the electrolytic oxidation of hydroxylamine with anodes of different metals was as follows :

	Pt	Cu	Fe	N	Co	Pb	C	Graphite
$NaNO_2$.	35·10	33·51	41·13	44·49	45·44	21·66	8·06	31·18
$NaNO_3$.	17·09	16·06	1·53	5·53	9·74	32·10	35·59	32·49

Thus, copper and platinum give similar results ; the nitrite formation is greater with iron, nickel, and cobalt, and the nitrate formation less. The gases were mainly nitrous oxide and nitrogen with a small proportion of oxygen. N. D. Zelinsky and S. G. Krapiwin showed that the decomposition of hydroxylamine into acid and base does not occur in soln. with methyl alcohol as solvent. J. Tafel showed that an aq. soln. of hydroxylamine sulphate in presence of 20–50 per cent. of sulphuric acid is not reduced at a copper cathode. O. Flaschner observed some reduction in dil. sulphuric acid soln. J. Tafel and H. Hahl found that reduction always takes place when the sulphuric acid conc. in the layer of electrolyte in contact with the cathode is reduced beyond a certain point, and when there is no excess of acid ; in other words, when hydroxylamine sulphate itself is electrolyzed, the reduction is quantitative. These results are most readily accounted for on the view that only free hydroxylamine (produced in this case by partial hydrolysis of the sulphate), but not the hydroxylammonium ion, $NH_3OH^{\cdot}$, is reduced at a copper cathode. The subject was discussed by H. E. Patten, V. Rothmund and O. Flaschner, and J. Tafel—*vide supra.*

The electrical conductivity was measured by W. H. Ross, who found that in all cases the conductivity of the salt soln. was increased with time, especially with the more dil. soln. This is due to the decomposition of the salts under the influence of the platinum-black of the electrodes; with polished electrodes, the effect is considerably smaller. The base itself is oxidized even more rapidly than the salts. The soln. are in all cases decomposed by the platinum electrodes, and G. M. J. MacKay showed that tin does not decompose the soln. at all, while copper decomposes the soln. completely. The order in which the metals were found to decompose the soln. is: tin, platinum, silver, nickel, mercury, and copper. The electrical conductivity of hydroxylamine, using tin electrodes, in terms of mercury at 18°, with v vols. of soln. per mol, is as follows:

v	0·0994	0·5	1·0	5·0	10	20	50	100	200	500
μ	0·031	0·02	0·051	0·098	0·28	0·40	0·52	0·76	1·3	1·4

There is therefore a minimum mol. conductivity between the $2N$- and $10N$-conc., which may indicate that at high concs., hydrates are formed which are dissociated on further dilution, but this point was not further investigated. The sp. conductivity in reciprocal ohms of pure hydroxylamine at a temp. slightly above 33° was found to be approximately 83×10^{-6}, a value which lies between that of liquid ammonia at 30°, 150×10^{-6}, and that of hydrazine hydrate, 34×10^{-6}. W. A. Noyes and J. H. Hibben made some transport experiments with some ionizable derivatives of hydroxylamine. K. Winkelblech found 2·5 per cent. hydrolysis in aq. soln. of hydroxylamine hydrochloride at 25° with soln. containing a mol of the salt in 1024 litres of water; and V. H. Veley, 8·1 per cent. at 15° with a mol of salt in 10,000 litres. E. O. Ellingson obtained results about 0·3 to 2·6 per cent. higher than J. Thomsen for the heats of neutralization of hydroxylamine with acids. E. O. Ellingson found for hydroxylamine and hydrochloric acid, concentration 1 : 50, 9483 cals., and conc. 1 : 200, 9292 cals.; for hydroxylamine and sulphuric acid, conc. 1 : 50, 11,445 cals., and conc. 1 : 200, 11,071 cals.; for hydroxylamine and trichloracetic acid, conc. 1 : 100, 9681 cals.; and conc. 1 : 200, 9280 cals.

The chemical properties of hydroxylamine.—According to C. A. Lobry de Bruyn, free hydroxylamine may produce a blister if a drop rests on the skin for a short time, but no ill-effects were noticed from the vapours when working with this substance. G. Bertoni and C. Raimondi observed that intravenous or subcutaneous injections have a poisonous action, and nitrous acid can then be detected in the blood. A. Pasquali said that the salts of hydroxylamine are poisonous, but large doses are needed to produce fatal effects; he found the lethal dose for dogs to be 0·032 grm. per kgrm. of body weight. R. Cuisa and R. Luzzatto say that hydroxylamine is four to five times as powerful a poison as nitrous acid. T. L. Brunton and T. J. Bokenham found that hydroxylamine reduces the blood press. like amyl nitrite. L. Lewin, C. Binz, and G. Bertoni and C. Raimondi noted the changes produced in blood corpuscles by hydroxylamine. W. Lossen said that the alcoholic soln. irritates and reddens the skin. The toxic action of hydroxylamine on bacteria, and infusoria was observed by G. Bertoni, W. Gibbs and E. J. Reichert, P. J. Eichkoff, O. Löw, G. Marpmann, W. B. Brodie, and A. Pasquali; M. Raciborsky, however, showed that hydroxylamine is assimilated by some fungi. V. Meyer and E. Schulze found that hydroxylamine salts retard the development of plants or else kill them.

C. A. Lobry de Bruyn said that if hydroxylamine be of a high degree of purity, it may be kept for months without decomposition; its decomposition is favoured by alkalies, so that the glass vessels in which it is to be kept must be well washed with acids. A number of salts also favour the decomposition of hydroxylamine. According to J. W. Brühl, the solid is stable at low temp., and molten under-cooled hydroxylamine, at 0°, does not decompose. Decomposition commences at about 10° with the formation of small bubbles of gas—mostly nitrogen; the decomposition at about 20° proceeds steadily, and this the faster, the higher the temp. C. A. Lobry de Bruyn said that nitrogen and nitrous oxide are formed by the spontaneous decomposition of hydroxylamine or ammonium nitrite. According to K. A. Hofmann and F. Kroll, the slow decomposition of hydroxylamine hydrochloride at about 150°, takes place in accordance with the equations: $3NH_2.OH=N_2+NH_3+3H_2O$ and $4NH_2.OH=N_2O+2NH_3+3H_2O$. The addition of basic substances represses the second in favour of the first change to an extent which is less than would be expected, whereas acidic substances displace the action in the contrary direction. Nitrous acid or nitrite is produced by the acid or alkaline fusion of hydroxylamine. It is therefore probable that hydroxyhydrazine is produced initially from 2 mols. of hydroxylamine and subsequently converted into the diamide of nitrous acid, $OH.N(NH_2)_2$; this is hydrolyzed to ammonia and nitrous acid (or nitrosyl acid in conc. acid soln.) which, with unchanged hydroxylamine, yields nitrous oxide. Confirmation of this hypothesis is found in the observation that nitrous oxide is not formed in the presence of sufficient alkali or of carbamide. In alkaline soln. the diamide of nitrous acid suffers mainly intramolecular decomposition, $OH.N(NH_2)_2=N_2+NH_3+H_2O$, accompanied by the subsidiary change: $OH.N(NH_2)_2+NaOH=NaNO_2+2NH_3$. A. Kurtenacker and F. Werner found that the course of the decomposition of hydroxylamine in alkaline soln. depends on the conc. of the alkali, on the temp., and on the nature of any catalyst present. The higher the alkali conc.—in the absence of a catalyst or in the presence of pumice, platinized pumice, or platinum gauze—the smaller the proportion of nitrous oxide and the greater the proportion of nitrogen formed. In the presence of platinum-black, the proportion of nitrous oxide formed increases slightly with a rise in the conc. of alkali. Catalysts in general cause an increase in the yield of nitrous oxide for any given conditions, platinum-black being the most efficient catalyst in this respect, giving a yield up to 63 per cent. of the weight of hydroxylamine. The reaction probably proceeds through the formation of the labile condensation product, hydroxyhydrazine, which may react with a further mol. of hydroxylamine, giving ammonia and nitrogen: $3NH_2OH=NH_3+N_2+3H_2O$; or may decompose into ammonia and nitroxyl, the latter being converted into hyponitrous acid, which decomposes into nitrous oxide and water: $4NH_2OH=2NH_3+N_2O+3H_2O$.

Hydroxylamine in **oxygen** produces a white cloud without becoming hot. Hydroxylamine on filter paper or asbestos, in **air**, becomes heated owing to rapid oxidation; the free base absorbs oxygen from air, forming nitrous acid. The oxidation is favoured if traces of free alkali be present. Dil. aq. soln., free from salts, are fairly stable even if the temp. be raised; but conc. soln. were found by E. Divers and T. Shimidzu, W. Lossen, and E. Frémy to decompose readily on exposure to air. The aq. soln. decomposes more rapidly in the presence of sodium or potassium hydroxide; and V. Meyer and E. J. Constam found the presence of ammonia favours the decomposition so much so that an aq. soln. of hydroxylamine which had stood beside conc. aq. ammonia over-night was completely decomposed. S. S. Kolotoff said that the products of the decomposition are ammonia, nitrogen, nitrous oxide, water, and, added W. R. Dunstan and T. S. Dymond, nitrous acid. The reaction was examined by S. M. Tanatar, and V. Meyer. O. Löw said that the presence of platinum-black hastens the decomposition, and, added S. M. Tanatar, favours the formation of nitrous oxide. A. Findlay and W. Thomas found the vol. of gas evolved by an aq. soln. of hydroxylamine in the presence of colloidal platinum was much reduced in the presence of dextrin, starch, gelatin, peptone, and, to a less degree, of ferric hydroxide soln. and this the more the greater the proportion of dextrin, starch, or gelatin present. Thus, if v c.c. denotes the vol. of gas evolved in a given time, without and with the addition:

Time (minutes)	1	5	10	15	20	95	30	35	40
v	0·30	2·25	6·50	12·25	19·00	25·25	30·75	35·55	40·33
v 1% starch .	0·30	2·25	6·00	10·80	16·50	22·25	27·75	32·20	37·60
3% starch .	0·20	1·75	4·25	7·70	11·70	16·20	21·00	25·00	28·00

The colloidal addition thus retards the catalytic activity of the platinum possibly by adsorption of the colloid by the platinum. W. Strecker and H. Thienemann observed that hydroxylamine hydrate radily reacts with **ozone,** forming hydroxylamine nitrate. The reaction is not complete and an excess of ozone is needed.

According to C. A. Lobry de Bruyn, hydroxylamine is miscible with **water** in all proportions ; the aq. soln. has no smell ; and it reacts alkaline. When the aq. soln. is distilled, ammonia is evolved, and undecomposed hydroxylamine and water pass into the receiver without leaving any residue in the retort. E. Barrett studied the dissociation of the salts of hydroxylamine in aq. soln. A drop of hydroxylamine mixed with 5 c.c. of a 2·5 per cent. soln. of **hydrogen dioxide** gives off bubbles of gas, and the soln. contains nitric acid. C. Wurster found that the oxidation of hydroxylamine sulphate by hydrogen dioxide at 40° furnishes sulphuric acid, water, and a quantitative yield of nitric acid ; likewise also with hydroxylamine chloride. An aq. soln. of phenol, hydroxylamine salt, and hydrogen dioxide give nitrosophenol ; and phenylhydrazine is converted by hydrogen dioxide into benzene and diazobenzeneimide. S. M. Tanatar said that in neutral soln. the gas evolved is a mixture of equal parts of oxygen and nitrogen, and in alkaline soln. almost pure nitrogen. E. Francke also studied the action of hydrogen dioxide on hydroxylamine. A. Thum noted the formation of a hyponitrite in the oxidation of hydroxylamine by hydrogen dioxide.

According to C. A. Lobry de Bruyn, hydroxylamine inflames in a stream of **chlorine** gas ; **bromine** decomposes the base without incandescence, forming hydrogen bromide, nitrogen, and water ; and **iodine** acts in an analogous way. T. Haga represented the reaction with iodine: $2NH_2OH+2I_2=N_2O+4HI+H_2O$. According to K. A. Hofmann and F. Kroll, the oxidizing or reducing action of hydroxylamine depends on the conditions ; in feebly acidic soln., ferric chloride gives ferrous chloride and nitrous oxide, whereas in conc. sulphuric or phosphoric acid soln., ferrous sulphate gives ferric and ammonium sulphates. In acetic acid soln., hydroxylamine is oxidized by iodine, but not so in mineral acid soln., for in conc. hydrochloric acid, hydroxylamine liberates iodine from hydriodic acid. F. Raschig suggested that the first stage of the oxidation of hydroxylamine by iodine is the formation of *dihydroxylhydrazine*:

$$\begin{array}{l} \text{H—N—OH} \\ \text{H—}\dot{\text{N}}\text{—OH} \end{array}$$

which immediately passes into *dihydroxyldiimide,* HO.N : N·OH ; and this in turn into nitrous oxide, N_2O. C. T. Dowell found that an excess of chlorine on a soln. of hydroxylamine in carbon tetrachloride forms nitrogen trichloride. The base forms a salt when it reacts with **hydrochloric acid.** Hydroxylamine is vigorously oxidized by **sodium hypochlorite** ; W. R. Dunstan and E. Goulding studied the action of **hydriodic acid** and of the **metal iodides** on hydroxylamine. F. Raschig showed that the hypochlorites of sodium, potassium, and calcium are reduced by hydroxylamine salts and **iodic acid** is also reduced—according to E. Frémy, in acid or neutral soln. R. P. Sanyal and N. R. Dhar observed that in the reduction of iodic acid with hydroxylamine hydrochloride there is a period of induction, but the electrical conductivity of the system did not attain a maximum until after the appearance of the iodine ; this is attributed to the decomposition of the hydroxylamine in aq. soln. as well as to the oxidation of iodine. R. Möhlau and C. Hoffmann found that with a 10 per cent. soln. of **hypochlorous acid,** an aq. soln. is decomposed with the intermediate formation of NH_2OCl, **chlorohydroxylamine,** $NH_2OH+HOCl=NH_2OCl+H_2O$; and $2NH_2OCl=N_2+Cl_2+2H_2O$. F. Raschig said that hypochlorous acid can oxidize hydroxylamine completely to nitric acid. According to C. A. Lobry de Bruyn, no action occurs when **chlorates,** or **perchlorates** or **bromates** are mixed with hydroxylamine, but if a drop of sulphuric acid be present, the mixture inflames. The base reduces **iodates** and **periodates** without inflammation. D. Vitali represented the reduction of iodates by hydroxylamine sulphate by $2(NH_2OH)_2H_2SO_4+KIO_3=N_2O+N_2+6H_2O+KI+2H_2SO_4$; $2KI+H_2SO_4=K_2SO_4+2HI$; and $5HI+HIO_3=3I_2+3H_2O$; with bromates, bromine is separated only when the soln. is heated; and with chlorates, no reaction was observed. M. Schlötter represented the quantitative reduction of bromates in acid soln.: $4NaBrO_3+12NH_2OH=4NaBr+18H_2O+3O_2+6N_2$. The reaction was studied by A. Kurtenacker and J. Wagner, F. Fichter and W. F. Tschudin, and by E. Rupp and H. Mäder. According to P. Jannasch and A. Jahn, the reduction of the iodates, bromates, and chlorates occurs more readily in acid soln. than in neutral or ammoniacal soln. The reduction of the chlorates in ammoniacal soln. is very feeble. E. C. Gilbert observed that there is a variation in the reaction with hydroxylamine and an acidic soln. of potassium bromate depending on the order of mixing. G. R. Levi represented the reaction with equimolar parts of hydroxylamine hydrochloride and a **chlorite** in neutral soln.: $NH_2OH{\cdot}HCl+NaClO_2=NaCl+Cl+NO+2H_2O$; and with an excess of the hydroxylamine salt: $2NH_2OH.HCl+NaClO_2=NaCl+N_2O+3H_2O+2HCl$. Powdered **sulphur** does not react with hydroxylamine. S. M. Tanatar, and F. Raschig noted that **sulphur dioxide** is oxidized to ammonium sulphate, and F. Raschig obtained hydroxylamine sulphaminates by the action of sulphur dioxide on hydroxylamine salts—*vide* sulphur dioxide. The **persulphates** are reduced by hydroxylamine salts. A. Gutmann represented the reaction with **sodium tetrathionate**, in acid soln. by $H_2S_4O_6+NH_2OH+H_2O=2H_2SO_4+2S+NH_3$; and in alkaline soln. by $Na_2S_4O_6+2NH_2OH+3NaOH=2Na_2S_2O_3+NaNO_2+3H_2O+NH_3$. O. Hinsberg found that **selenium dioxide** is reduced to selenium by aq. soln. of the base. According to C. A. Lobry de Bruyn, **ammonia** is absorbed to the extent of 20 per cent. by molten hydroxylamine; and S. S. Kolotoff observed no reaction when ammonia is heated for 100 hrs. in a sealed tube with hydroxylamine at 100°. For the action of **hydrazine**, *vide infra*. **Nitrous oxide** and **nitric oxide** are without action on the base, but liquid nitrous oxide is reduced. G. Oesterheld, and E. J. Joss represent the reaction with **hyponitrous acid**: $H_2N_2O_2+2NH_2OH=2N_2+4H_2O$. According to V. Meyer, **nitrous acid** decomposes an aq. soln. of the base: $NH_2OH+HNO_2=2H_2O+N_2O$. S. M. Tanatar found the reaction between hydroxylamine chloride and sodium nitrite occurs with difficulty in the presence of magnesia, calcium oxide or carbonate, and cadmium or zinc oxide; if the acid soln. of the hydroxylamine chloride be neutralized, it does not react with sodium nitrite. The reaction with hydroxylamine sulphate and nitrite is spontaneous and vigorous in conc. soln.; in dil. soln., the reaction is very slow with cold soln. W. Wislicenus, and C. Paal showed that some hyponitrous is formed as an intermediate product of the reaction, and it can be isolated, particularly, said S. M. Tanatar, if chalk be present in the system. C. Montemartini measured the speed of the reaction between hydroxylamine chloride and sodium nitrite: $NH_2OH{\cdot}HCl+NaNO_2=N_2O+NaCl+2H_2O$. If k be the velocity constant; C (grams. per 100 c.c.), the conc. of the hydroxylamine t minutes from the beginning; and C_0 the conc. at the beginning when $t=0$, $dC/dt=kC^2$, and $k=(C^{-1}-C_0{}^{-1})t^{-1}$. If C_0 be greater than 0·036 at 16°, k increases with time, and when $k=0{\cdot}226$, at 25°, it remains nearly constant. When t is greater than 400, the value of k decreases. The presence of either sodium sulphate or sodium chloride decreases the speed of the reaction considerably, as shown by the decreased values of k. The product $K\eta$ is not constant for soln. with varying amounts of sodium chloride—here η denotes the viscosity constant of the soln., but $k\eta^2$ is approximately constant when 16–24 per cent. of sodium chloride or 8–14 per cent. of sodium sulphate is present. If n denotes the ratio of the number of mols. of the one salt—hydroxylamine chloride—sodium chloride—then kn was not constant. With hydroxylamine hydrochloride, the velocity of the reaction is less than when the sulphate is used, and still less than with the nitrate. With lithium, sodium, and potassium nitrites, k decreases as the at. wt. of the metal increases, and k is greater for strontium nitrite than for that of barium. Hydroxylamine probably reduces nitric acid: $2HNO_3+2NH_2OH=2HNO_2+N_2O+3H_2O$.

According to C. A. Lobry de Bruyn, no reaction occurs when hydroxylamine is mixed with ordinary **phosphorus**. Hydroxylamine hydrochloride reacts slowly with **phosphorus pentachloride** in the cold, but at 100°, the action is energetic—hydrogen chloride is given off, and ammonium chloride and some nitrogen are formed. Inflammation occurs when the base is mixed with **phosphorus trichloride** or the pentachloride. E. Ebler studied the action of hydroxylamine chloride on soln. of **arsenic acid,** and on **bismuth salts**; A. Gutmann said that with **sodium arsenite** the reaction is symbolized: $NH_2OH+Na_3AsO_3=Na_3AsO_4+NH_3$, with the side reaction: $3NH_2OH=NH_3+N_2+3H_2O$. Hydroxylamine does not react with **carbon monoxide,** but **carbon dioxide** is absorbed in great quantities with a slight rise of temp., and the formation of a liquid which does not freeze at —10°. **Carbon disulphide** unites with hydroxylamine, forming a substance which slowly becomes yellow, then orange, and there is then a separation of sulphur. Hydroxylamine is miscible in all proportions with **methyl or ethyl alcohol,** and the conc. soln. on cooling may deposit acicular or scaly crystals; it is slightly soluble in **propyl alcohol**; boiling **ether** dissolves about 1·2 per cent. of the base, and on cooling needle-like crystals separate; **acetic ether** dissolves 1·6 per cent. of the base at ordinary temp.; and **chloroform,** 0·3 per cent. With chloroform, a white amorphous compound with hydroxylamine is formed. Hydroxylamine is virtually insoluble in **benzene** or **petroleum ether.**

The action of hydroxylamine or its salts on *carbonyl* compounds was studied by S. F. Acree and co-workers; on *acetone,* by P. Landrieu, and I. Schöttle; on *ketones,* by R. Ciusa and A. Terni, P. I. Petrenko-Kritschenko and S. Lordkipanidze, C. Moureu and I. Lazennec, G. Minunni and C. Carta-Satta, and A. Janny; on *ethylene oxide,* by L. W. Jones and G. R. Burns; on *cyanogen bromide,* by H. Wieland and H. Bauer; on *potassium ferrocyanide,* by K. A. Hofmann and H. Arnoldi, and A. Thum; on *nitro-prussides,* by J. Giral-Pereira, and J. G. Pereira; on *santonin,* by L. Francesconi and G. Cusmano; on *fats,* by E. Morelli; on *dimethylpyronedicarboxylate,* by C. Palazzo; on *peroxydase,* by A. Bach; on *cyanoamides,* by J. von Braun and R. Schwarz; on *unsaturated acids,* by T. Posner, and C. D. Harries and W. Haarmann; on *bromonitrocamphane,* by M. O. Forster; on *aldehydes,* by K. Hess and C. Uibrig; on *oxaloacetic acid,* by H. J. H. Fenton and H. O. Jones; on *formic acid,* by G. Schröter and M. Peschkes; on *ethyl phenylpropionate,* by S. Ruhemann and H. E. Stapleton; on *methyl, ethyl, and propyl iodides,* by W. R. Dunstan and E. Goulding, A. Hantzsch and W. Hilland, and C. A. Lobry de Bruyn; on *thiocarbamide,* by W. R. G. Atkins and E. A. Werner, and E. Tiemann; on *phenyl carbamide,* by E. O. Beckmann; on *trinitrotoluene,* by M. Giua; on *nitrosobenzene,* by E. Bamberger and E. Renauld; on *nitrobenzene,* by A. Angeli, and E. Bamberger and E. Knecht; on *acetamide,* by M. O. Forster; on *ethyl formate,* by G. Schröter; on *lactones,* by L. Francesconi and G. Cusmano; on *coumarins,* by T. Posner and R. Hess; on *acetylene,* by E. Oliveri-Mandala; on *lutidone,* by I. Schöttle; on *benzoylhydracetic acid,* I. Schöttle; on *benzene sulphonate,* by A. Seyewetz and L. Poizat; on *phenyl hydrazine,* by E. Fischer; on *zinc ethyl* and *magnesium alkyl halides,* by F. Ebler and R. L. Krause; on *metaphosphoric esters* and *phosphorous esters,* by W. Strecker and H. Heuser; etc.

C. A. Lobry de Bruyn found that **sodium** reacts with hydroxylamine with incandescence; in ethereal soln., hydrogen is developed and a white, voluminous, hygroscopic **sodium hydroxylamite,** NH_2ONa, is formed, which sometimes catches fire when exposed to air. E. Ebler and E. Schott found that when hydroxylamine is treated with calcium filings at 50°, a white powder of **calcium hydroxylamite,** $Ca(ONH_2)_2$, is formed which explodes at 180°. It is slowly hydrolyzed by moist air, and reacts with water: $Ca(ONH_2)_2+2H_2O=Ca(OH)_2+2NH_2OH$—*vide infra.* C. A. Lobry de Bruyn reported that no reaction occurs with hydroxylamine and **magnesium** powder. D. Vitali found that magnesium acts on a soln. of hydroxylamine chloride, forming hydroxylamine and hydrogen. According to E. Ebler and E. Schott, the base is reduced when heated with *zinc* dust, forming zinc oxide and ammonia; sometimes the mixture inflames, at other times it explodes. The immediate product of the reaction is not $ZnO : NH_3$, but rather **zinc hydroxylamite,**

$Zn(ONH_2)_2.3NH_2OH$. This salt can be purified by recrystallization from absolute alcohol. When partially immersed in hydrazine hydrate, and partially exposed to air, it gives off hydrogen, and forms **zinc hydrazinocarboxylate dihydrazinate,** $(NH_2.NH.CO.O)_2Zn(NH_2NH_2)_2$. It does not give a precipitate with a soln. of a chloride of an alkaline earth; and when the soln. is boiled, the substance is hydrolyzed, and the carbonate of the alkaline earth is precipitated. There are also indications of the formation of very unstable **ferrous hydroxylamite** by the action of **iron** on hydroxylamine salts.

C. A. Lobry de Bruyn found that molten hydroxylamine does not react with solid **sodium hydroxide,** but dissolves therein, forming a mass which attracts oxygen from the air. W. Lossen showed that the alkali hydroxides react with an aq. or alcoholic soln. of the hydroxylamine salts liberating hydroxylamine which then reacts with the excess of alkali-lye, forming ammonia, nitrous oxide, and nitrogen. According to M. Berthelot, M. Berthelot and G. André, the main reaction is symbolized: $3NH_2OH=NH_3+N_2+3H_2O$, and there is at least one side reaction: $4NH_2OH=2NH_3+N_2O+3H_2O$—the gaseous product contains about 95 per cent. of nitrogen and 5 per cent. of nitrous oxide. The thermal value of the first reaction is 57 Cals. per mol, and of the second, 45·2 Cals. If platinum black be employed as catalyst, the side reaction predominates and becomes the main reaction, for the gaseous product then contains 15 per cent. of nitrogen and 85 per cent. of nitrous oxide. In neutral solutions, hydroxylamine decomposes very slowly. A. Thum found that hydroxylamine is oxidized by **cupric oxide,** and E. Francke studied the reaction with the copper oxides in some detail. C. A. Lobry de Bruyn said that hydroxylamine is inflamed in contact with **barium oxide**; W. Lossen, that **barium hydroxide** reacts with aq. or alcoholic soln. of hydroxylamine salts as in the case of the alkali hydroxides. K. A. Hofmann and V. Kohlschütter digested finely powdered **calcium oxide,** or **calcium carbide** with a soln. of hydroxylamine in methyl alcohol, and obtained a white powder, which is partly decomposed by water at ordinary temp. into calcium hydroxide and hydroxylamine, and which reduces ammoniacal soln. of copper or silver salts. E. Ebler and E. Schott regard the product as a mixture of calcium hydroxylamite and hydroxide. W. Lossen found that **magnesium oxide** does not decompose a soln. of hydroxylamine chloride at ordinary temp., but when warmed, ammonia gas is vigorously evolved. C. A. Lobry de Bruyn said that a mixture of hydroxylamine with **barium or lead dioxide** inflames.

Hydroxylamine was found by C. A. Lobry de Bruyn to dissolve many salts—**potassium iodide, bromide, and cyanide** are copiously dissolved; while **sodium or barium nitrate,** and **sodium or potassium chloride** are dissolved to the extent of 11–14 per cent. The soln. of barium nitrate and **potassium sulphate** in hydroxylamine do not give a precipitate of barium sulphate when they are mixed. F. L. Hahn and K. Brunngässer found that the solubility of **barium carbonate** is increased more than 30-fold in $0{\cdot}25M$-NH_2OH. Hydroxylamine can unite with many salts, forming compounds in which it appears to act as **hydroxylamine of crystallization** like water in hydrated salts—*e.g.* L. Crismer prepared $ZnCl_2.2NH_2OH$, $CdCl_2.2NH_2OH$, and $BaCl_2.2NH_2OH$; H. Alexander, $PtCl_2.2NH_2OH,Pt(OH)_2.4NH_2OH$, and $PtSO_4.4NH_2OH.H_2O$; H. Goldschmidt and K. L. Syngros, compounds with the carbonates of zinc, iron, manganese, and nickel; W. Feldt, compounds with cobalt and manganese salts; and R. Uhlenhuth, $NiSO_4.6NH_2OH$. A number of **complex salts** have been made, thus, W. Meyeringh prepared $(NH_3OH)Al(SO_4)_2.12H_2O$; $(NH_2OH)Cr(SO_4)_2.12H_2O$; and $(NH_2OH)Fe(SO_4)_2.12H_2O$. A double salt is formed with magnesium sulphate, $Mg(NH_3OH)_2(SO_4)_2.6H_2O$, but not with ferrous and zinc sulphates or with magnesium and manganese chlorides. G. Antonoff has described a number of these salts with magnesium and the alkaline earth chlorides. Hydroxylamine is **amphoteric** in that it behaves towards the alkalies like a weak acid, forming **hydroxylamites,** and towards the bases like ammonia, forming a series of **salts.** Hydroxylamine generally acts as a **reducing agent**, particularly in acid soln., but as shown by A. Piccini, L. Marino, and S. M. Tanatar, it can also act as an **oxidizing agent**, for in alkaline soln. it oxidizes the alkali nitrites, nitric oxide, and the hyponitrites ; and in acid soln. stannous chloride forms stannic chloride; sulphurous acid gives ammonium sulphate ; and sulphuric acid soln. of vanadium trioxide are converted to vanadium tetroxide.

C. A. Lobry de Bruyn found that anhydrous **copper sulphate** causes hydroxylamine to inflame, and the hydrated salt is vigorously reduced. W. Lossen, E. Ebler, G. von Knorre and K. Arndt, E. Francke, H. O. Jones and F. W. Carpenter, E. Péchard, W. Feldt, A. Thum, C. Kjellin, W. Meyeringh, and E. Frémy noted the reduction of soln. of copper salts by hydroxylamine. The precipitate first formed is grass-green, and it then becomes copper-red and forms a colourless soln. with an excess of hydroxylamine, without the evolution of a gas. When the soln. is exposed to air, the surface acquires a dirty bluish-green separation which again passed into soln. when the liquid is agitated. When the soln. is heated, a gas is evolved, and if it be mixed with a little alkali-lye, or baryta-water, it furnishes an orange-yellow precipitate, probably of cuprous hydroxide. Alkaline soln. of copper oxide give a precipitate of cuprous hydroxide with hydroxylamine. J. Donath said that almost all the nitrogen is evolved as nitrous oxide, very little ammonia is formed. Ammoniacal soln. of copper oxide are decolorized by hydroxylamine and alkali-lye, giving a yellow precipitate when treated with alkali-lye. The precipitate obtained by adding an alcoholic soln. of hydroxylamine to a soln. of copper sulphate is less variable than that produced by an aq. soln. The first precipitate is grass-green, it then changes to dark azure-blue with an excess of hydroxylamine. When dried over sulphuric acid, the precipitate is green, and when boiled with water, it gives off a gas and forms cuprous oxide. A. Kurtenacker and F. Wengefeld found that copper sulphate in acidic soln. of hydroxylamine yields mainly nitrous and nitric oxides and a little nitrogen ; in strongly alkaline soln., nitrous oxide is the main product. Powdered **silver nitrate** was found by C. A. Lobry de Bruyn to be reduced by hydroxylamine, forming silver. A. Lainer, E. Ebler, W. Lossen, and E. Frémy said that aq. soln. of silver salts are reduced to metal by soln. of hydrazine salts. The precipitate first obtained is black, and this soon gives off gas copiously and is transformed into the metal. W. Lossen, and E. Ebler found that a soln. of **gold chloride** is likewise reduced to metal by hydroxylamine salts.

W. Lossen observed that no precipitation occurs when a soln. of hydroxylamine is added to one of a **calcium, strontium, barium, or magnesium salt.** A soln. of **zinc sulphate** gives a precipitate not soluble in an excess of the hydroxylamine soln. E. Ebler studied the action of the chloride on cadmium salts. C. A. Lobry de Bruyn found that anhydrous hydroxylamine has no perceptible action on the anhydrous sulphates of zinc or magnesium. W. Lossen, E. Ebler, and E. Frémy observed that hydroxylamine soln. has a strong reducing action on **mercury salts.** The precipitate with mercuric chloride is at first yellow ; it then rapidly changes into mercurous chloride ; and if excess of hydroxylamine be present, it gives off gas, leaving mercury as a residue. M. Adams prepared mercury compounds with hydroxylamine analogous to the mercuriammonium compounds (**4.** 31, 31). N. R. Dhar studied the induced reaction involving the effect of hydroxylamine on the reduction of mercuric chloride by oxalic acid. Soln. of **aluminium salts,** say alum, give precipitates with an aq. soln. of hydroxylamine, insoluble in an excess of precipitant—*vide supra,* hydroxylamine—alum. According to A. Benrath and K. Ruland, **ceric sulphate** in the presence of sulphuric acid oxidizes hydroxylamine to nitrogen and nitrous oxide (69 to 73 per cent.). E. Ebler studied the action of hydroxylamine hydrochloride on **tin salts.** C. Kjellin found that **stannous hydroxide** and hydroxylamine react in accord with the equation: $Sn(OH)_2+NH_2OH+H_2O=Sn(OH)_4+NH_3$. W. Lossen noted that soln. of **lead salts**—*e.g.* lead acetate—give a precipitate with hydroxylamine not soluble in an excess. A. Gutmann represented the oxidizing action of hydroxylamine on **sodium arsenite :**

$NH_2OH+Na_3AsO_3=Na_3AsO_4+NH_3$, which runs concurrently with $3NH_2OH=NH_3+N_2+3H_2O$. E. Ebler, G. von Knorre and K. Arndt, and K. A. Hofmann and F. Küspert observed that **vanadium pentoxide** is reduced by hydroxylamine with the evolution of nitrogen; as indicated above, hydroxylamine was found by A. Piccini to oxidize a sulphuric acid soln. of **vanadium trioxide** into the tetroxide. According to A. Kurtenacker and F. Werner, alkaline soln. of hydroxylamine are reduced quantitatively to ammonia by vanadyl salts, quinquevalent molybdenum salts, and ferrous sulphate. In dil. acidic soln., cuprous sulphate and molybdenum sulphate have the same effect, ferrous sulphate and cuprous chloride are without action, and vanadyl sulphate causes a catalytic decomposition into ammonia, nitrogen, and nitrous oxide. In very strongly acidic soln., only the molybdenum salt has any action, causing a slow but eventually complete reduction to ammonia. Cuprous oxide induces a slow catalytic decomposition of alkaline hydroxylamine soln., the velocity of the action increasing with the alkalinity. K. A. Hofmann and V. Kohlschütter prepared a complex salt with **metavanadic acid**; a drop of anhydrous hydroxylamine on powdered **potassium dichromate** produces a violent explosion; **ammonium dichromate** and chromic acid act a little less vigorously. F. Raschig noted that chromic acid and the chromates are reduced by soln. of hydroxylamine salts. According to A. Thum, a cold, neutral soln. of **potassium chromate** is not changed by a soln. of hydroxylamine, but when heated, the colour darkens, and if a little sulphuric acid be present, gas is evolved and a brown precipitate is formed; if more acid be added, the precipitate dissolves. G. von Knorre and K. Arndt found that with mercuric chloride in alkaline soln., nitrous oxide and nitrogen are formed, and nitrites are produced. A. Kurtenacker and F. Wengefeld showed that in the oxidation of hydroxylamine by potassium dichromate in weak acid soln., half the hydroxylamine is oxidized to nitric acid, and the proportion of nitric oxide increases, and that of nitrous oxide decreases as the acidity of the soln. is diminished; in strong acid soln., the proportion of hydroxylamine oxidized to nitric acid sinks to about 25 per cent. and the gas produced is nitrous oxide; and in alkaline soln., the formation of nitric acid is still further reduced, while the gaseous products are nitrogen and nitrous oxide. The oxidation of hydroxylamine is complete only in weak acidic soln.; in alkaline soln., it varied from 47 to 64 per cent., and in strong acid soln., it was about 78 per cent. E. Francke studied the oxidizing action of chromic oxide on hydroxylamine. G. von Knorre and K. Arndt, G. Bertoni, W. Meyeringh, and W. O. de Coninck found that nitrous fumes and nitrogen gases are evolved; and W. Lossen, that **chrome-alum** gives a precipitate with a soln. of hydroxylamine, not soluble in an excess of the precipitant. W. Meyeringh prepared hydroxylamine chrome-alum. According to K. A. Hofmann and V. Kohlschütter, **molybdic, tungstic, and uranic acids,** or **molybdates, tungstates, and uranates,** form complexes with hydroxylamine. The action of hydroxylamine hydrochloride on molybdates and tungstates was examined by E. Ebler. A. Kurtenacker and F. Wengefeld said that molybdic acid has no action on hydroxylamine in alkaline soln., but in acidic soln. it acts catalytically, forming ammonia, nitrogen, and nitrous and nitric oxides. According to A. Kurtenacker and R. Neusser, the decomposition of hydroxylamine in the presence of a vanadate in acid soln. yields nitrogen and nitrous oxide, the proportion of the latter first decreasing and then increasing with decreasing acidity. The simultaneous reduction of the vanadate takes place. In neutral soln., nitrous oxide only is produced, but in alkaline soln. a catalytic decomposition to nitric and nitrous oxides and nitrogen takes place, the proportions of the first two decreasing with increasing alkalinity. The oxygen in these gases must be derived from the hydroxylamine, and the latter is reduced to ammonia. When the vanadate is replaced by ammonium molybdate, nitric oxide, nitrogen, and nitrous oxide are produced, the first-named decreasing in amount as the soln. passes from the acid to the alkaline state. The evolution of gas corresponds with about half the hydroxylamine used; the molybdates behave like the vanadates in strongly alkaline soln. A. Kurtenacker and F. Wengefeld found that quinquevalent molybdenum, quadrivalent vanadium, and bivalent iron reduced hydroxylamine to ammonia.

C. A. Lobry de Bruyn found that when solid hydroxylamine is brought into contact with solid **potassium permanganate,** there is immediately produced a white flame. F. Raschig suggested that the oxidation of hydroxylamine in dil. sulphuric acid soln. by potassium permanganate passes successively through the stages: *dihydroxylhydrazine,* 2(HO).NH.NH(OH), *vide supra,* iodine—dihydroxyldiimide, nitrous oxide and an *iso*-nitrogen tetroxide, which would have the constitution:

$$\begin{matrix}O\\ \vdots\\ O\end{matrix}\!>N.N<\!\begin{matrix}O\\ \vdots\\ O\end{matrix}$$

and which, on hydrolysis, yields nitric acid and nitrogen: $5N_2O_4+4H_2O=8HNO_3+N_2$. Complete oxidation to nitric acid cannot be effected with the permanganate. In a dil. alkaline soln., F. Raschig suggested that *tetrahydroxylhydrazine,* $(HO)_2N.N(OH)_2$, is formed and immediately broken down into nitrous oxide and nitrite. A. Kurtenacker and R. Neusser observed that the products of the reaction are greatly influenced by the acidity or alkalinity of the soln., and to a less extent by the conc. In acidic or strongly alkaline soln., potassium permanganate oxidizes hydroxylamine to nitrous oxide, and nitric acid or a nitrate, but in slightly alkaline soln., some nitrogen is produced. C. A. L. de Bruyn found that anhydrous **manganese sulphate** has no perceptible action on hydroxylamine—*vide* the nitrate and sulphate of hydroxylamine. C. Kjellin found that the amount of ammonia produced by the action of **manganese hydroxide** on hydroxylamine is negligibly small. W. Feld prepared a complex salt with manganese sulphate. Alkaline soln. of potassium permanganate are reduced by hydroxylamine salts, and A. Thum said that the hydroxylamine is converted into nitrohydroylaminic acid:

$$O<\!\begin{matrix}N{-}OH\\ \vdots\\ N{-}OH\end{matrix}$$

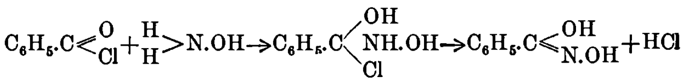
as an intermediate product of the oxidation. The reaction was studied by E. Francke. F. Raschig, and S. M. Tanatar found that soln. of **ferric salts** are reduced to ferrous salts by hydroxylamine salts, though W. Meyeringh was able to prepare a hydroxylamine ferric-alum. A. Kurtenacker and R. Neusser found that the sole oxidation product with ferric salts in acidic soln. is nitrous oxide, but the action is not complete unless the ferric salt is present in considerable excess. In neutral soln., a little nitrogen is produced, but in alkaline soln., the ferrous hydroxide formed is oxidized by the hydroxylamine. A. Kurtenacker and F. Wengefeld found the ferric hydroxide produces nitrous oxide and ammonia, catalytically in alkaline soln. E. Francke, W. R. Dunstan and T. S. Dymond, and F. Haber showed that if **ferrous hydroxide** be suspended in alkali-lye or in an ammoniacal soln., the hydroxylamine is reduced to ammonia, and red ferric hydroxide is formed. If the product be dissolved in acid and treated with hydroxylamine, the ferric salt is reduced back to the ferrous state. E. Ebler and E. Schott did not agree with F. Haber, but the discrepancy is attributed to F. Haber having used dil. soln. C. Kjellin represented the reaction: $H_2O+NH_2OH+2Fe(OH)_2=NH_3+2Fe(OH)_3$. W. Lossen observed that **ferrous salts** give a precipitate with an aq. soln. of hydroxylamine, which is insoluble in an excess of the precipitant; A. D. Mitchell said that the reaction, after the early stages, is directly proportional to the conc. of the hydroxylamine and to the square of the conc. of the ferric chloride, and inversely proportional to the conc. of the ferrous salt, and to the square of the H-ion conc. It is assumed that the reaction is: $2Fe^{\cdot\cdot\cdot}+NH_3OH^{\cdot}\rightleftharpoons Fe^{\cdot\cdot}+2H^{\cdot}+(NOH,Fe,H)^{\cdot\cdot\cdot}\rightarrow N_2O$, etc., where the bracketed term represents an intermediate complex. The temp. coeff., 6·5 per 10°, is abnormally high. The salt effect is negative, for the speed of the reaction is depressed by the addition of indifferent salts. W. Lossen observed that hydroxylamine gives a precipitate, insoluble in excess, when added to a soln. of **nickel sulphate.** R. Uhlenhuth prepared a complex salt. C. A. Lobry de Bruyn found that anhydrous hydrazine is without action on anhydrous nickel sulphate, but anhydrous **cobalt sulphate** is transformed into a voluminous brown mass. W. Feldt prepared a complex salt with cobalt sulphate. According to E. Frémy, and W. Lossen, a prolonged heating is necessary for an aq. soln. of hydroxylamine to reduce a soln. of platinum tetrachloride to the metal. H. Alexander prepared some complexes with platinum salts and hydroxylamine—*vide supra.*

Some reactions of analytical interest.—The reactions of hydroxylamine are in many cases quite distinctive and are shown by relatively small quantities of the compound; hence, they can be used for its identification. Hydroxylamine can be detected by its reducing action on alkaline or ammoniacal soln. of copper oxide, since it forms a red precipitate of cuprous oxide recognizable, it is said, if but one part of hydroxylamine be present in 100,000 parts of water. A. Angeli proposed to neutralize the soln. with either hydrochloric acid or sodium hydroxide; add about a milligram of sodium nitroprusside to about 2 c.c. of soln. in a test-tube; make the soln. alkaline with about 1 c.c. of N-NaOH; shake; and warm the soln. rapidly to 100° on a water-bath. The presence of as little as 0·01 per cent. of hydroxylamine will give a magenta coloration. W. C. Ball said that if hydroxylamine is boiled with a drop of yellow ammonium sulphide until sulphur begins to separate, and then mixed with 2 or 3 c.c. of conc. aq. ammonia and the same vol. of alcohol, a purple-red coloration sensitive to one part of hydroxylamine in 500,000 parts of soln. will appear. Hydrazine does not show any coloration under the same conditions. E. Bamberger, and G. W. Pucher and H. A. Day, treated soln. with sodium acetate and benzoyl chloride when hydroxylamine forms benzhydroximic acid which gives a violet-red coloration with ferric chloride. W. M. Fischer said that 0·00005 per cent. of hydroxylamine in the presence of ammonium or hydrazine salts can be detected by adding 1–2 drops of 2½ per cent. yellow ammonium sulphide soln., and 1–2 c.c. of ammonia to 1–5 c.c. of the soln. to be tested. In presence of hydroxylamine an unstable purple colour is developed in the soln. on shaking in presence of air, and its appearance is greatly accelerated by adding 1–2 drops of 0·1N-manganous sulphate soln. which appears to act as an oxidizing catalyst. W. N. Hirschel and J. A. Verhoeff said that an ammoniacal soln. of diacetylmonoxime in presence of hydroxylamine condenses to dimethylglyoxime, which in presence of nickel gives the well-known red precipitate. A conc. of 1 mg. per c.c. of hydroxylamine gives the precipitate at once in the cold; for small quantities, it is necessary to boil, cool, and neutralize with acetic acid, and in this way 0·01 mg. can be detected. C. A. Lobry de Bruyn determined the free hydroxylamine in aq. soln., by titration with standard acid, using methyl orange as indicator. Hydroxylamine can be determined in a soln. by adding a known amount of a substance—*e.g.* ferric sulphate (W. Meyerlingh, A. Leuba, F. Raschig, and L. Amat); vanadic sulphate (K. A. Hofmann and F. Küspert); silver nitrate (G. Denigès); or titanium trichloride (A. Stähler, W. C. Bray and coworkers, and E. Knecht)—and determining volumetrically the amount which has not been reduced in the remaining soln. adding an excess of permanganate soln., and back titrating with arsenious acid (A. Thum, and K. A. Hofmann and F. Küspert). It is also determined by titration with a standard soln. of potassium permanganate after the addition of sodium oxalate (L. J. Simon); and by titration of the alkaline soln. with mercury acetamide (M. O. Forster). H. O. Jones and F. W. Carpenter poured the hydroxylamine into an ammoniacal soln. of copper oxide, or one of copper potassium carbonate (A. Soldaini). The mixture was boiled and the precipitated cuprous oxide filtered, washed, and added to a soln. of ferric-alum in a flask filled up with carbon dioxide. The resulting ferrous sulphate was titrated with potassium permanganate.

The constitution of hydroxylamine.—Analyses, and the mol. wt. determination by the f.p. method agree with the empirical formula NH_3O, which may be represented graphically by $H_3{\equiv}N{=}O$, or $H_2{=}N{-}OH$, according as the nitrogen be quinque- or tervalent. It is generally supposed that hydroxylamine has a constitution related to that of ammonia, with but one hydrogen atom of the ammonia replaced by hydroxyl. This agrees with its formation from nitric acid: $HO{-}NO_2+6H\rightarrow HO{-}NH_2+2H_2O$; a reaction analogous with the formation of amine bases from the nitro-compounds $R{-}NO_2+6H\rightarrow R{-}NH_2+2H_2O$; and, like the amines and ammonia, hydroxylamine unites directly with acids to form salts. If hydroxylamine be constituted $H_2{=}N{-}OH$, the hydrogen atoms are not of equal value, since one is not related to the nitrogen atom the same as the other two. Consequently, the compound might be expected to yield two different substitution products, according as the hydrogen of the hydroxyl group or the hydrogen of the amido- or NH_2-group be replaced by an eq. radicle. H. Remy, and H. Henstock discussed the electronic structure. W. Lossen worked for many years *Ueber die Strukturformel des Hydroxylamins und seiner amidartigen Derivate.* At first, it was thought that just as the acid chlorides—like benzoyl chloride, $C_6H_5CO.Cl$—react with ammonia, forming acid amides—like benzamide, $C_6H_5CO.NH_2$—as symbolized: $C_6H_5CO.Cl+2NH_3\rightarrow C_6H_5CO.NH_2+NH_4Cl$, so do acid chlorides react with hydroxylamine, giving what are called **hydroxylamic acids**—*vide infra*—or, as A. Werner prefers to call them, **hydroxamic acids**—for example, with benzoyl chloride, *benzhydroximic acid*, $C_6H_5CO.HNOH$, is formed: $C_6H_5CO.Cl+2NH_2OH \rightarrow C_6H_5CO.NH_2O+NH_2OH.HCl$. From this point of view, the hydroximic acids bear the same relation to hydroxylamine as the acid amides bear to ammonia. By a similar reaction, a second and third group have been introduced into hydroxylamine, forming the di- and tri- substituted hydroxylamines. By boiling these substituted compounds with dil. hydrochloric acid, hydroxylamine is restored. *Dibenzhydroximic acid* should have two isomeric forms in accord with the fact that there are two kinds of hydrogen atoms in hydroxylamine—namely $RH{=}N{-}OR$ and $R_2{=}N{-}OH$—and in agreement with this, two forms were found to exist. All this agrees better with the formula $H_2{=}N{-}OH$ than with $H_3{\equiv}N{=}O$; but the different isomers of the tri-substituted acids weakened confidence in the argument. Only one form of *tribenzhydroxylamine*, $(C_6H_5)_2N.OC_6H_5$, should be possible, whereas three isomers are known to exist; again, two *dibenzanisyl-hydroxylamines* are theoretically possible—$R_bR_a{=}N{-}OR_b$ and $R_bR_b{=}N{-}OR_a$—whereas three have been actually found. Consequently, either the fundamental assumption as to the constitution of hydroxylamine is wrong, and each of the three hydrogen atoms has a different substitution value, or else the constitution of the base changes when its hydrogen atoms are replaced by three radicles, so that each of the three nitrogen valencies acts in a different manner. In later years, W. Lossen came to the latter conclusion; he supposed that the monosubstitution product has a constitution typified by

$$C_6H_5{-}C{<}\begin{smallmatrix}N.OH\\OH\end{smallmatrix}$$

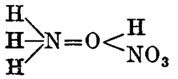
and not by $C_6H_5.CO.NH.OH$. The two tautomeric forms suggested by the first two formulæ have not been discovered, and the experimental evidence does not decide which of the two is preferable, for, as N. V. Sidgwick has said: "There are arguments of no great weight on either side." With either structure, it follows that the hydroximic acids are not formed by reactions analogous with the action of acid chlorides on ammonia. In each case, a transient addition product is probably first formed, and this breaks down into hydroximic acid and hydrogen chloride, thus:



$$C_6H_5.C{<}\begin{smallmatrix}O\\Cl\end{smallmatrix}+\begin{smallmatrix}H\\H\end{smallmatrix}{>}N.OH\rightarrow C_6H_5.C\begin{smallmatrix}OH\\NH.OH\\Cl\end{smallmatrix}\rightarrow C_6H_5.C{<}\begin{smallmatrix}OH\\N.OH\end{smallmatrix}+HCl$$

In this manner, it can be seen that although the three replaceable hydrogen atoms may appear to have a different position in the mol., the cases of isomerism, inexplicable on the first hypothesis, can be readily explained without assuming that hydroxylamine itself has a structure different from that generally accepted, viz. $H_2{=}N{-}OH$. The subject was discussed by A. Hantzsch and A. Werner, R. Behrend and E. König, K. Auwers and V. Meyer, L. W. Jones, and A. Michael.

S. S. Kolotoff supposed that because he could not make the reaction $NH_2OH+NH_3\rightarrow N_2H_4+H_2O$ progress by heating the mixture under different conditions, hydroxylamine does not contain a hydroxyl group. This argument does not appear to have much weight. E. Wagner tried to explain the oxidizing and reducing properties of hydroxylamine by assuming it to be derived from hydrogen dioxide by the substitution of one hydroxyl group by one amido-group. This would make the formula of hydroxylamine depend upon that of hydrogen dioxide. If the latter be $HO{=}OH$, that of hydroxylamine may be supposed to be $H_2N{\equiv}OH$; and if $H_2{=}O{=}O$, hydroxylamine may be supposed to be $H_3N{=}O$. The optical measurements of R. Bach, and J. W. Brühl make the formula $H_2N:NH_2$ for hydrazine and of $H_2N{=}OH$ for hydroxylamine improbable. E. Ebler and E. Schott have brought forward evidence to show that both the constitutional formulæ $H_2{=}N{-}OH$ and $H_3{\equiv}N{=}O$ may be correct under special conditions. Thus, F. Haber regarded hydroxylamine to be constituted $H_2{=}N{-}OH$ when it acts as a reducing agent; and as $H_3{=}N{=}O$ when it acts as an oxidizing agent. E. Ebler and E. Schott concluded that there is a kind of desmotropism. **In alkaline solutions, hydroxylamine plays the rôle of an amido-acid $H_2{=}N{-}OH$, and acts as a reducing agent; while in acid solutions, it behaves like basic ammonia oxide $H_3{\equiv}N{=}O$, and acts as an oxidizing agent.** In the latter case, hydroxylamine salts resemble the oxonium compounds in containing a quadrivalent oxygen atom.



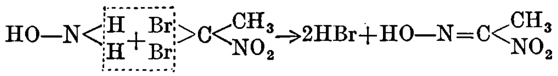
$\begin{matrix}H\\H\\H\end{matrix}{>}N{=}O{<}\begin{matrix}H\\NO_3\end{matrix}$

Hydroxylamine nitrate.
[Hydroxylamine a base.]

$\begin{matrix}H\\H\end{matrix}{>}N{-}O{-}Na$

Sodium hydroxylamate.
[Hydroxylamine an acid.]

The formation of oximes and hydroximic acids from hydroxylamine, and of, say, *ethylnitrolic acid*, $CH_3.C(NO_2)NOH$, from dibromonitroethane, $CH_3.CBr_2(NO_2)$, and hydroxylamine, observed by V. Meyer:



$$HO{-}N{<}\boxed{\begin{matrix}H\\H\end{matrix}+\begin{matrix}Br\\Br\end{matrix}}{>}C{<}\begin{matrix}CH_3\\NO_2\end{matrix}\rightarrow 2HBr+HO{-}N{=}C{<}\begin{matrix}CH_3\\NO_2\end{matrix}$$

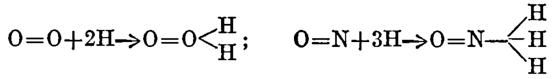
and the formation of *iso-diazobenzene*, $C_6H_5.N:NOH$, from nitrosobenzene, C_6H_5NO, and hydroxylamine, observed by E. Bamberger and E. Renauld:

$$C_6H_5{-}N{=}\boxed{O+H_2}{=}N{-}OH\rightarrow H_2O+C_6H_5{-}N{=}N{-}OH$$

favour the amido-formula, and these reactions all take place in alkaline solutions. In these cases, hydroxylamine is not an oxidizing agent in the sense of the reaction $H_3N{=}O\rightarrow NH_3+O$, but it appears to act in this way in acid solutions. For instance, hydroxylamine oxidizes a sulphuric acid soln. of vanadium sesquioxide to vanadic acid, and it exerts a similar action on the sesquioxides of titanium and molybdenum:

$$H_3N{=}\boxed{O+Ti_2O_3}\rightarrow NH_3+2TiO_2$$

According to S. M. Tanatar, also, sulphurous acid is oxidized to sulphuric acid by hydroxylamine hydrochloride, and the latter is at the same time reduced to ammonia: $H_2SO_3+NH_3O.HCl\rightarrow(NH_4)HSO_4+HCl$. Several organic compounds, too, are oxidized in an analogous manner. Just as hydrogen dioxide can be regarded as a reduction product of oxygen (1. 14, 13), so, in acid soln., hydroxylamine is formed as a reduction product of the nitric oxide



$$O{=}O+2H\rightarrow O{=}O{<}\begin{matrix}H\\H\end{matrix};\qquad O{=}N+3H\rightarrow O{=}N{-}{<}\begin{matrix}H\\H\\H\end{matrix}$$

and not as an oxidation product of ammonia or hydrazine.

Doubled formulæ like that of J. Donath $H_4{\equiv}N{=}O_2{=}N{\equiv}H_4$; and the imaginary anhydride $H_2{=}N{-}O{-}N{=}H_2$ of E. Divers were abandoned after C. A. Lobry de Bruyn had determined the mol. wt. of hydroxylamine to be 33.

§ 24. The Salts of Hydroxylamine

The preparation of normal **hydroxylamine chloride,** $(NH_3OH)Cl$, or, as it is also represented, $NH_2OH.HCl$, *hydroxylamine hydrochloride* or *chlorohydrate*, has been indicated in connection with the preparation of hydroxylamine by the reducing action of hydrochloric acid and tin, or stannous chloride on nitric acid, or nitrites; and electrolytically. W. Lossen [1] also obtained it by the neutralization of the free base with hydrochloric acid. M. Adams obtained the salt by double decomposition between barium chloride and hydroxylamine sulphate. W. L. Semon used a modification of E. Divers' process in which the conversion of sodium carbonate, first into a mixture of hydrocarbonate and hydrosulphite, and then into hydrosulphite alone is carried out prior to the addition of the sodium nitrite, as a result of which the time required for the complete operation and the amount of cooling necessary are considerably reduced. Further, the sodium hydroxylaminedisulphonate is converted directly into acetoxime as recommended by F. Raschig, and this is then hydrolyzed by hydrochloric acid and the required hydroxylamine hydrochloride obtained after distilling off the acetone as indicated by A. Janny. Under these conditions, a product is obtained free from ammonium salts and with a yield of 53–77 per cent.—*vide supra*, hydroxylamine. It was also prepared by P. J. Eichkoff.

The salt occurs in thin plates by cooling the hot, sat., alcoholic soln.; in small crystals, by the slow evaporation of the soln.; and in plates, by the conc. of its aq. soln. The monoclinic prisms were found by V. von Lang to have the axial ratios $a:b:c=2{\cdot}0108:1:3028$, and $\beta=92°\ 57'$. The crystals show no crystallographic relations with those of ammonium chloride, although O. Lehmann said that the two salts crystallize in *regelmässiger Anlagerung.* H. Schiff and U. Monsacchi gave 1·676 for the sp. gr. at 17°/4°; and for the soln., they gave $D=1+0{\cdot}00425w+0{\cdot}0_595w^2$, where w denotes the percentage content of hydroxylamine chloride in the soln. During the dissolution, there is a contraction of —0·432 with soln. containing 40 per cent. of salt—sp. gr. 1·1852—an expansion of 0·192 with 20 per cent. soln.—sp. gr. 1·0888—and an expansion of 0·261 with 10 per cent. soln.—sp. gr. 1·0437. G. Tammann found the vap. press. of water by soln. with 10·48, 19·80, and 34·24 grms. of salt per 100 grms. of water to be depressed 34·2, 65·6, and 109·5 mm. respectively. W. Lossen said the salt does not lose weight when dried at 120° over conc. sulphuric acid; and it melts at about 151° with rapid decomposition, forming water, hydrogen chloride, ammonium chloride, nitrogen, and possibly nitrous oxide. P. J. Eichkoff said that it melts at 151° and decomposes at a higher temp.; W. H. Ross gave 157° for the m.p., and represented the decomposition: $3(NH_3OH)Cl=NH_4Cl+2HCl+N_2+3H_2O$. M. Berthelot gave $(2H_2,Cl,Nl,O)=70{\cdot}8$ Cals. for the heat of formation; and J. Thomsen, 18·5 Cals. for the heat of neutralization with hydrochloric acid. H. Remy measured the electrolytic transport of water in soln. of hydroxylamine hydrochloride. E. Ebler studied the mol. dispersion of aq. soln. of hydroxylamine hydrochloride. W. H. Ross gave for the electrical conductivity, μ, at 18°, in terms of mercury, with soln. of vol. v per mol of salt:

v . .	2	5	10	20	50	100	500	1000	5000	10,000
μ . .	73·3	80·5	86·6	90·9	95·8	98·9	101·5	107·6	111·6	112·4

E. Divers and T. Haga noted the gradual decomposition of the salt when it is impure. The salt readily dissolves in water and there is a marked fall of temp., and H. Schiff and U. Monsacchi said that at 17°, 100 parts of water dissolve 83·3 parts of salt, The dried salt is only sparingly soluble in absolute alcohol; and is precipitated from its soln. by ether. The hydrolysis of the aq. soln. observed by K. Winkelblech, and V. H. Veley has been discussed in connection with the base itself. The same remark applies to the actions of hydroxylamine hydrochloride on hydrogen dioxide, by C. Wurster; on alcoholic hypochlorites, by W. O. de Coninck; on the alkali nitrites, by S. M. Tanatar; on soln. of copper salts by G. von Knorre and K. Arndt, and E. Ebler; on acid soln. of ferric salts, by W. Meyeringh; and on the salts of silver, gold, cadmium, mercury, bismuth, tin, and arsenic, and on the molybdates, tungstates, and vanadates by E. Ebler. W. Lossen, and E. J. Maumené found nitric oxide and other gases are given off when the chloride is triturated with cupric oxide. Ammonium chloride was produced by the oxidation of crocionic acid by hydroxylamine chloride (R. Nietzki and T. Benckiser), of oxanthranol (E. von Meyer), and of triphenylvinylalcohol (H. Biltz). J. A. Muller found that the hydrochloric acid in hydroxylamine hydrochloride can be titrated with standard sodium hydroxide by using phenolphthalein as indicator provided carbon dioxide is absent. The free base does not act on that indicator.

By mixing a soln. of 42 grms. of hydroxylamine hydrochloride, in 48 c.c. of water, with a soln. of 20 grms. of hydroxylamine in 260 grms. of absolute alcohol; washing the precipitate with alcohol, then with ether, and finally drying in a current of air, W. Lossen obtained **hydroxylamine hemichloride,** $2NH_2OH.HCl$. It is also called basic hydroxylamine hydrochloride. He obtained the same product by adding ether to the mother-liquid obtained in preparing the normal chloride. The salt appears in rhombic prisms when a soln. in the smallest possible amount of hot water is cooled, or when the soln. is evaporated over conc. sulphuric acid. The crystals precipitated by alcohol are tabular. The salt melts at about 85° with the evolution of gas. The crystals are deliquescent in moist air; and they are slightly soluble in alcohol, but not in ether. The aq. soln. gives off hydroxylamine at ordinary temp. W. Lossen also reported hydroxylamine ditritachloride, $3NH_2OH.2HCl$, to be formed from a mixed soln. of the normal and the hemichloride. The rhombic crystals melt at about 95° with the evolution of gas. The hemichloride crystallizes from an aq. soln. of the ditritachloride. The deliquescent crystals are but sparingly soluble in alcohol, and insoluble in ether. W. R. Dunstan and E. Goulding stated that the evidence in favour of the existence of this product as a chemical individual is not free from objections.

M. Adams prepared normal **hydroxylamine bromide,** $NH_2OH.HBr$, by adding barium bromide to a soln. of hydroxylamine sulphate in excess. The filtered soln. was evaporated to dryness, and the residue extracted with absolute alcohol. The purified crystals are stable in the absence of air; the impure crystals become brown when exposed to light. The salt is readily soluble in water, and insoluble in ether. It is a stronger reducing agent than the chloride. It forms double salts with mercury and cadmium bromides. M. Adams prepared **hydroxylamine hemibromide,** $2NH_2OH.HBr$, or basic hydroxylamine bromohydrate, by adding hydroxylamine to a conc. alcoholic soln. of the normal salt; and by the action of the normal salt on mercuric oxide: $HgO+4(NH_2OH.HBr)=HgBr_2+H_2O+2(NH_2OH)_2HBr$. The white tabular crystals are readily soluble in water, but insoluble in ether or ligroïn.

R. Wolffenstein and F. Groll made normal **hydroxylamine iodide,** $NH_2OH.HI$, in colourless needles, by evaporating a soln. of eq. proportions of hydroxylamine and hydriodic acid, in vacuo, at 26°. The salt was also made by M. Adams, who said that the salt is very unstable, deliquescent in air, and furnishes a yellow soln. The instability, said W. R. Dunstan and E. Goulding, is due to the reducing action of hydrogen iodide on hydroxylamine. R. Wolffenstein and F. Groll recrystallized the salt from methyl alcohol. When warmed, iodine separates, and at 83°–84°, the salt decomposes with explosive violence. W. R. Dunstan and E. Goulding prepared

hydroxylamine hemiiodide, $2NH_2OH.HI$, by evaporating an alcoholic soln. of eq. proportions of hydroxylamine and methyl iodide or hydriodic acid, or by evaporating the mother-liquid obtained in the preparation of the tritaiodide; M. Adams obtained it from an ethereal soln. of the normal iodide. The tabular crystals are deliquescent; they are readily soluble in water, and in methyl or ethyl alcohol, but are not soluble in ether. When recrystallized from water, iodine is set free. The aq. soln. is acid, and is a strong reducing agent. The salt is best recrystallized from methyl alcohol, for then only a very small proportion of salt is decomposed. W. R. Dunstan and E. Goulding could not make the 3 : 2 salt: *hydroxylamine ditritaiodide;* but they obtained **hydroxylamine tritaiodide,** $3NH_2OH.HI$, by dissolving theoretical proportions of hydroxylamine and hydriodic acid in methyl alcohol, and fractionally precipitating the salts with ether so as to separate the normal and tritaiodides. O. Piloty and O. Ruff made the salt by the action of butyl iodide on hydroxylamine. W. R. Dunstan and E. Goulding said that the white tabular crystals are stable in dry air. O. Piloty and O. Ruff gave 103°–104° for the m.p. According to W. R. Dunstan and E. Goulding, at about 100°, the salt suddenly decomposes: $3NH_2OH.HI=NH_4I+N_2+3H_2O$; when recrystallized from hot methyl alcohol, or from water, there is a loss of hydroxylamine and the hemiiodide is formed; the tritaiodide is produced if an excess of hydroxylamine be always present. The aq. soln. has an acid reaction, and is a strong reducing agent.

W. Lossen prepared normal **hydroxylamine sulphate,** $(NH_2OH)_2H_2SO_4$, by evaporating a mixture of the normal chloride with the calculated quantity of sulphuric acid, and extracting the residue with alcohol. The methods of R. Preibisch, F. Raschig, E. Divers and T. Haga, J. Tafel, and C. F. Böhringer—indicated in connection with the preparation of hydroxylamine—can be employed. W. Lossen said that the cooling of the hot aq. soln. furnishes prismatic crystals, which, according to V. von Lang, belong to the monoclinic system, and, according to J. H. E. Dathe, to the triclinic system. W. Lossen found that the sulphate dried over conc. sulphuric acid does not lose in weight at 110°, and melts with decomposition at about 170°; S. S. Kolotoff found a loss in weight occurs between 125° and 130°, and added that the loss is rapid at 136°; and R. Preibisch gave 140° for the m.p. and the temp. of decomposition: $4(NH_2OH)_2H_2SO_4=4(NH_4)HSO_4+N_2+2NO+6H_2O$. W. H. Ross gave 163° for the m.p. and represented the accompanying decomposition; $3(NH_3.OH)_2SO_4=(NH_4)_2SO_4+2SO_2+2N_2O+8H_2O$. J. Thomsen, and M. Berthelot gave for the heat of formation, $(N_2,4H_2,S,3O_2)=280{\cdot}20$ Cals., for the heat of neutralization $(NH_2OH,\frac{1}{2}H_2SO_4)=10{\cdot}79$ Cals.; and for the heat of soln., —5'8 Cals. (M. Berthelot) or —9·6 Cals. (J. Thomsen). J. Tafel found that electrolytic reduction of hydroxylamine occurs at the copper cathode, only when the conc. of the sulphuric acid about the cathode falls below a certain critical value—*vide supra,* hydroxylamine. W. H. Ross gave for the electrical conductivity, μ, at 18° in terms of mercury with soln. containing a mol of salt in v vols.

v . .	5	10	20	50	100	500	1000	5000	10,000
μ . .	63·8	71·6	80·5	92·0	97·7	109·3	113·0	118·9	120·3

E. Divers and T. Haga said that the salt is not hygroscopic, but H. Schröder said that when triturated, the powder becomes moist owing to the decomposition brought about by the friction. The salt is soluble in water; E. Divers and T. Haga said that 133 parts of salt dissolve in 100 parts of water. M. Adams found that 100 grms. of water dissolve S grm. of salt:

	−8°	0°	10°	20°	30°	40°	50°	60°	90°
S . .	30·7	32·9	36·6	41·3	44·1	48·2	52·2	56·0	68·5

R. Preibisch found the salt to be insoluble in alcohol and ether, and M. Adams said that when dry, the salt is insoluble in absolute alcohol and almost insoluble in 95 per cent. alcohol. W. Lossen found that alcohol precipitates the salt in needles from its conc. aq. soln. The aq. soln. has an acid reaction, but R. Preibisch found that it would not drive carbon dioxide completely from the carbonates in the cold. The reactions indicated in connection with hydroxylamine were often produced by the sulphate. The reducing action on the iodates, bromates, and chlorates was discussed by D. Vitali, M. Schlötter, and P. Jannasch and A. Jahn. Similarly, C. Wurster discussed the oxidizing action of hydrogen dioxide. According to R. Preibisch, the crystals dissolve in conc. sulphuric acid without developing any gas. J. Tafel said that the sulphate is so stable in 50 per cent. sulphuric acid, that the soln. can be warmed to 40° without decomposition. A. Angeli and F. Angelico studied the decomposition of hydroxylamine sulphate by persulphates. R. Preibisch found a copious evolution of gas when hydroxylamine dissolves in conc. nitric acid. J. Tafel found that a soln. of hydroxylamine sulphate in 50 per cent. sulphuric acid is not changed in the cold by the addition of 50 per cent. nitric acid; a soln. of 0·64 grm. of hydroxylamine sulphate, 0·65 grm. nitric acid, and 10 c.c. of 50 per cent. sulphuric acid is not changed by keeping 7 hrs. at 15°; when warmed to 41°–42°, much gas is given off; if 40 per cent. sulphuric acid is used, decomposition occurs at 24°–27°; with 30 per cent. sulphuric acid, decomposition begins at 100° with explosive violence. V. Meyer, and W. Wislicenus discussed the action of nitrous acid or nitrites—*vide* hydroxylamine. R. Preibisch found hydroxylamine sulphate is not perceptibly altered by conc. aq. ammonia; but it dissolves in soda-lye, and the soln. smells of ammonia. J. Tafel found that a soln. of hydroxylamine sulphate in 50 per cent. sulphuric acid is quite stable in the presence of powdered copper sulphate or metallic copper. R. Preibisch said that silver nitrate produces a white precipitate and when ammonia is added much gas is evolved, and silver is deposited. Gas is vigorously evolved when the aq. soln. of hydroxylamine sulphate is treated with potassium dichromate —the gas contains nitrogen and nitric oxide in the ratio 1 : 2. A similar evolution of gas occurs with manganese dioxide and sulphuric acid. These reactions were also studied by G. Bertoni. Complex salts with the metal sulphates were studied by W. Meyeringh, M. Adams, and E. Knövenagel and E. Ebler.

J. Tafel believed that the soln. of hydroxylamine sulphate in 50 per cent. sulphuric acid contained a salt $NH_2OH.H_2SO_4$, **hydroxylamine hydrosulphate.** A. Lidoff obtained this salt by the action of hydrosulphurous acid on potassium nitrite; and E. Divers, by digesting the normal chloride with the calculated quantity of sulphuric acid, and evaporating in cold air. The prismatic crystals are very deliquescent.

According to V. Meyer, no *hydroxylamine carbonate* has been produced; but H. Goldschmidt and K. L. Syngros prepared complex carbonates with zinc, manganese, iron, and nickel salts. W. Lossen treated hydroxylamine chloride with silver nitrate or hydroxylamine sulphate with barium nitrate, and on evaporating the filtered soln. obtained an oily liquid, which M. Berthelot and G. André cooled to —10°, and obtained a white, hygroscopic mass of **hydroxylamine nitrate,** $NH_2OH.HNO_3$. W. H. Ross could prepare only a viscid colourless liquid which he obtained by distilling the aq. soln. at 20 mm. press., and drying over phosphoric oxide. The salt melts at 48°, and decomposes at 100°, forming nitrogen, water, and oxygen. The heat of soln. is —5·9 Cals., the heat of neutralization, 9·2 Cals.; and the reaction $NH_2OH.HNO_3=N_2+O_2+2H_2O$ develops 51·4 Cals. at constant vol., or 50·3 Cals. at constant press. Hence the heat of formation is (N,3H,O) =86·4 Cals. W. H. Ross found the electrical conductivity, μ, at 18° on terms of mercury for soln. with a mol salt of in v vols., to be:

v .	5	10	20	50	100	500	1000	5000	10,000
μ .	—	106·7	112·6	119·1	122·8	127·1	129·9	134·0	135·5

The nitrate has a greater conductivity than the chloride which would not be expected from the behaviour of the corresponding salts of the alkalies. L. J. Simon represented the reaction with potassium permanganate by $2KMnO_4+5(NH_2OH.HNO_3)$ $=2Mn(NO_3)_2+2KNO_2+2N_2O+10H_2O$. W. Lossen reported normal **hydroxylamine orthophosphate,** $(NH_2OH)_3.H_3PO_4$, to be formed by mixing aq. soln.

of hydroxylamine chloride or sulphate and disodium hydrophosphate; and V. Kohlschütter and K. A. Hofmann, by mixing barium hydrophosphate and hydroxylamine sulphate, and adding alcohol to the filtered liquid; metaphosphoric acid neutralized with ammonia and mixed with hydroxylamine chloride furnishes this same salt. W. Lossen obtained small crystals which give only a syrupy mass when the aq. soln. is evaporated. W. H. Ross found that when the salt is heated in vacuo its decomposition is represented by $2(NH_2OH)_3.H_3PO_4 = 6NH_2OH + H_2O + H_4P_2O_7$. The electrical conductivity, μ, at 18° in terms of mercury for soln. with mol a of the salt in v vols. is as follows:

v	5	10	20	50	100	500	1000	5000	10,000
μ	19·8	22·0	23·6	24·7	25·5	26·4	26·6	27·0	27·1

The salt is only sparingly soluble in water, and according, to W. H. Ross, readily forms supersaturated soln. According to M. Adams, 100 grms. of water dissolve S grm. of salt:

	0°	10°	20°	30°	40°	50°	60°	70°	80°	90°
S	1·2	1·5	1·9	2·8	4·0	5·5	7·7	10·2	13·3	16·8

The hot aq. soln. reacts feebly acid. Dry ammonia gas liberates hydroxylamine, forming ammonium phosphate. The analogous ammonium salt, $(NH_3)_3.H_3PO_4$, is difficult to prepare, and the hydroxylamine salt may be constituted:

$$\begin{matrix} NH_4O \\ NH_4O(NH_2OH) \end{matrix} > PO_4{-}H$$

L. J. Simon represented the reaction with potassium permanganate $12KMnO_4 + 16\{(NH_2OH)_3H_3PO_4\} = 4Mn_3(PO_4)_2 + 6KH_2PO_4 + 2K_2HPO_4 + 2KNO_2 + 20N_2 + 3N_2O + 89H_2O$. A. P. Sabanéeff obtained **hydroxylamine dihydrophosphate,** $2NH_2OH.H_3PO_4$, or $(NH_3OH)_2HPO_4$, from monohydroxylamine phosphate by treatment with alcohol.

§ 25. Nitrohydroxylaminic Acid

If a soln. of hydroxylamine and sodium hydroxide in methyl alcohol be treated with methyl nitrate, a white powder is precipitated; it appears to be the sodium salt of an unstable acid—**nitrohydroxylaminic acid,** $H_2N_2O_3$—and it has the empirical formula $Na_2N_2O_3$. A. Angeli [1] has prepared a whole series of similar salts—*e.g.* potassium, alkaline earths, lead, cadmium, and cerium nitrohydroxylaminates—and also some inorganic esters—*e.g.* $H(C_2H_5)N_2O_3$; $H(C_6H_5)N_2O_3$; etc. The reaction between methyl nitrate, $CH_3.NO_3$, and hydroxylamine probably progresses:

$$CH_3.O—N{<}\begin{matrix}O\\O\end{matrix}+\begin{matrix}H\\H\end{matrix}{>}N.OH\rightarrow H_2O+CH_3.O—N{<}\begin{matrix}O\\N.OH\end{matrix}$$

Methyl nitrate. Methyl nitrohydroxylaminate.

and **sodium nitrohydroxylaminate,** NaO.NO : N.ONa, is formed by the displacement of the methyl group and hydrogen by sodium. The various reactions of the sodium salt agree with the structural formula:

$$NaO—N{<}\begin{matrix}O\\N—ONa\end{matrix}\quad\text{or}\quad\begin{matrix}NaO—N=O\\NaO—\ddot{N}\end{matrix}$$

If the sodium salt be treated with a mineral acid, there is a brisk effervescence, and nitric oxide is evolved $H_2N_2O_3\rightarrow 2NO+H_2O$, hence the compound has been regarded as a *hydrate of nitric oxide.* In this respect, nitrohydroxylaminic acid is brought into line with sulphurous and carbonic acids, both of which give the corresponding anhydrides when their salts are treated with acids:

$$\begin{matrix}HO\\HO\end{matrix}{>}SO$$

Sulphurous acid.

$$\begin{matrix}HO\\HO\end{matrix}{>}CO$$

Carbonic acid.

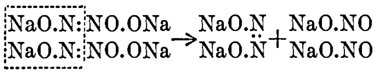
$$\begin{matrix}HO\\HO\end{matrix}{>}N_2O\quad\text{or}\quad\begin{matrix}HO—N=O\\HO—\ddot{N}\end{matrix}$$

Nitrohydroxylaminic acid.

Four years earlier than A. Angeli, A. Thum had found evidence of the existence of what he called *azoxyhydroxyl:*

$$O{<}\begin{matrix}\dot{N}—OH\\\dot{N}—OH\end{matrix}$$

but was unable to isolate it. A. Angeli and co-workers found that when sodium nitrohydroxylaminate is exposed to air, oxygen is rapidly absorbed, and a mixture of sodium nitrite and nitrate is formed. If a soln. of the sodium salt be allowed to stand in the cold, nitrous acid is slowly evolved; and if boiled, half the total nitrogen in the salt forms nitrous oxide, and half sodium nitrite: $2(NaO.N:NO.ONa)+H_2O\rightarrow N_2O+2NaNO_2+2NaOH$. When the sodium salt is warmed, it melts to a greenish liquid, forming a mixture of sodium nitrite and hyponitrite:



$$\begin{matrix}NaO.N:\\NaO.N:\end{matrix}\begin{matrix}NO.ONa\\NO.ONa\end{matrix}\rightarrow\begin{matrix}NaO.\ddot{N}\\NaO.\ddot{N}\end{matrix}+\begin{matrix}NaO.NO\\NaO.NO\end{matrix}$$

and the nitrous oxide formed in the previous reaction may be derived from sodium hyponitrite formed as an intermediate product of the decomposition. A. Angeli and F. Angelico prepared **potassium nitrohydroxylaminate,** $K_2N_2O_3$. F. Angelico and S. Fanara could not prepare *ammonium nitrohydroxylaminate,* or *hydrazine nitrohydroxylaminate.* When the sodium salt is treated with silver nitrate, yellowish **silver nitrohydroxylaminate,** AgO.N : NO.OAg, is formed, but being very unstable, it immediately breaks down into silver, nitric oxide, and silver nitrite: $AgO.N:NO.OAg\rightarrow Ag+NO+AgNO_2$. A. Angeli and G. Marchetti think that silver hyponitrite is formed as an intermediate product. The silver salt can be kept at a temp. below 0° for some time without decomposition. A. Angeli and F. Angelico, and F. Angelico and S. Fanara obtained **calcium nitrohydroxylaminate,** $CaN_2O_3.3\tfrac{1}{2}H_2O$;

strontium nitrohydroxylaminate, $SrN_2O_3.1\frac{1}{2}H_2O$; and **barium nitrohydroxylaminate,** $BaN_2O_3.H_2O$. F. Angelico and S. Fanara prepared **cadmium nitrohydroxylaminate,** $CdN_2O_3.H_2O$, by mixing equimolar quantities of the sodium salt and crystalline cadmium sulphate. It resembles the barium salt. It begins to decompose at 110°, and is completely decomposed at 200°. The salt becomes anhydrous at 100°. A. Angeli and F. Angelico prepared a basic **cerium nitrohydroxylaminate,** $Ce_2(N_2O_3)_3.Ce(OH)_3$; and **lead nitrohydroxylaminate,** PbN_2O_3. Again, when sodium nitroxylaminate is allowed to react with an aldehyde, say acetaldehyde, $CH_3.COH$, a sodium salt of **acetohydroximic acid** is formed:

$$CH_3{-}C{<}{}^{O}_{H}+O{=}N{<}{}^{N.ONa}_{ONa}\rightarrow CH_3{-}C{<}{}^{N.ONa}_{OH}+NaO{-}N{=}O$$

Acetaldehyde. Acetohydroximic acid.

The relative proportions of the two end-products show that the generalized reaction, so to speak, can be written $HO.N:NO.O\rightarrow HNO_2+NO$. The salt of acetohydroximic acid so obtained is hydrolyzed by boiling with acids, and hydroxylamine and an organic acid (acetic acid, $CH_3.CO.OH$) are formed:

$$CH_3{-}C{<}{}^{N.ONa}_{OH}+H_2O\rightarrow NH_2OH+CH_3{-}C{<}{}^{O}_{OH}$$

Acethoydroximic acid. Acetic acid.

The resultant effect, the end-products of the action of nitrohydroxylaminic acid on aldehyde can be generalized, so to speak, in a symbolic form by the equation:

$$\begin{matrix}N{-}OH\\ \ddot{N}O{-}OH\end{matrix}+H_2O\rightarrow\begin{matrix}NH_2OH\\ HNO_2\end{matrix}+O$$

for the oxygen atom has transformed the aldehyde group CO.H into the acid group CO.OH. These reactions are particularly interesting, for they show that the acid and its salts can decompose in at least six different ways which A. Angeli and F. Angelico summarize:

(1)	$2H_2N_2O_3=$	$4NO+2H_2O$	Free acid.
(2)		$2HNO_2+2NO+H_2$	Silver salt.
(3)		$2HNO_2+2NOH$	Sodium salt.
(4)		$2HNO_2+N_2O+H_2O$	Sodium salt.
(5)		$2HNO_2+H_2N_2O_2$	Sodium salt.
(6)	$+2H_2O$	$2HNO_2+2NH_2OH+O_2$	*Via* hydroximic acid.

Nitroyl, NOH.—A. Angeli in his extensive studies, *Ueber einige sauerstoffhaltige Verbindungen des Stickstoffs* (Stuttgart, 1908), found it convenient to call the group NOH, *nitrosyl*, a rather unfortunate term because the same word has long been used for the monad radicle NO; consequently, the term *nitrotyl*, or *nitroyl*, has been recommended in place of A. Angeli's nitrosyl. This group can act as a dyad radicle, forming with the aldehydes, R.COH, a **hydroximinic acid,** $R(OH)C{=}NOH$ (*vide supra*), which recalls the union of oxygen with an aldehyde to form an acid—*e.g.* acetaldehyde, $CH_3.COH$, unites with an atom of oxygen to form acetic acid, $CH_3.CO.OH$; hyponitrous acid is regarded as *dinitroyl*, HON : NOH, recalling the formation of a mol. of oxygen O : O, by the union of two oxygen atoms. Nitroyl is considered to be the anhydride of dihydroxyammonia: $NH(OH)_2\rightarrow H_2O+NOH$. A. Angeli considers *the formation of hydroximic acid by reaction with an aldehyde indicates the presence of the nitroyl group.* In virtue of this reaction, nitrohydroxylaminic acid is itself supposed to contain a nitroyl group. Neither dihydroxyammonia nor nitroyl has been isolated, but their presence has been inferred in the products of certain reactions. A. Kurtenacker and R. Neusser said that nitrogen is produced by the interaction of hydroxylamine with nitroyl.

When certain unsaturated carbon compounds—*e.g.* isosafrol, R.CH : CH.R—are treated with nitrous acid, they take up additively N_2O_3 to form the so-called *isonitrites*, and the isonitrites when treated with alkalies yield a soln. containing a nitro-derivative and nitroyl. In symbols:

$$R.CH:CH.R+N_2O_3\rightarrow R.\underset{NO}{CH}:\underset{NO_2}{CH}.R—R.CH:\underset{NO_2}{C}.R+NOH$$

A. Angeli found hyponitrous acid in the soln. containing the end-products of the reaction, and the soln. also gave the nitroyl reaction, and he also found that the products of the saponification of *potassium hydroxylamine sulphonate* gave reactions indicating the presence of sulphites, hyponitrites, and nitroyl; he represented the compound in question by $HO.N:SO(OK)_2$ in preference to E. Divers and T. Haga's formula $H(OH)N.SO.OH$; and he represented its decomposition by the equation $HO.N:SO(OK)_2\rightarrow NOH+SO(OK)_2$. Similar remarks apply to *benzene sulphohydroximic acid*, which O. Piloty symbolized $C_6H_5.SO_2.NH.OH$, but which A. Angeli prefers to represent $HO.N:SO(OH)C_6H_5$, because it, too, when hydrolyzed by an alkali gives the nitroyl reaction. The analogy in the constitution of these three substances is inferred from the similarity in their behaviour, and the presence of the nitroyl group in each is represented by the analogous formulæ:

$$\begin{matrix}N.OH\\ \ddot{N}O.OH\end{matrix}$$

Nitrohydroxylamine acid.

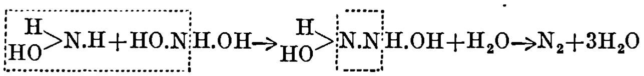
$$\begin{matrix}N.OH\\ HO.\ddot{S}O.OH\end{matrix}$$

Hydroxylamine sulphonic acid.

$$\begin{matrix}N.OH\\ C_6H_5.\ddot{S}O.OH\end{matrix}$$

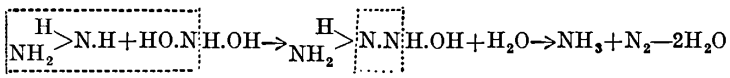
Benzene sulphohydroximic acid.

A. Angeli considers that in aq. soln. nitroyl probably exists as **nitroyl hydrate,** $NOH.H_2O$, which is isomeric, at any rate, with **dihydroxyammonia,** $(HO)_2NH$, and he further emphasizes the properties of nitroyl by showing that (i) it reacts with the alkyl iodides, forming oximes—characterized by the dyad group C : NOH—the same as are produced by the action of hydroxylamine on aldehydes. The oximes give hydroxylamine when hydrolyzed with acids; (ii) with nitrobenzene, $C_6H_5.NO$, it gives the same product $C_6H_5—NO{=}NOH$ as is obtained by the action of hydroxylamine on nitrobenzene; (iii) with hydroxylamine there is an evolution of nitrogen and formation of water:



$$\boxed{{}^{H}_{HO}{>}N.H+HO.N}H.OH\rightarrow {}^{H}_{HO}{>}\boxed{N.N}H.OH+H_2O\rightarrow N_2+3H_2O$$

and (iv) with hydrazine, $H_2N.NH_2$, it forms ammonia, nitrogen, and water:



$$\boxed{{}^{H}_{NH_2}{>}N.H+HO.N}H.OH\rightarrow {}^{H}_{NH_2}{>}\boxed{N.N}H.OH+H_2O\rightarrow NH_3+N_2—2H_2O$$

Summarizing the hydroxyl derivatives of ammonia, it will be seen that the introduction of hydroxyl increase the acidity and diminishes the stability of the resulting compounds:

TABLE XXVIII.—HYDROXYL DERIVATIVES OF AMMONIA.

—	NH_3 Ammonia.	NH_2OH Hydroxylamine.	$NH(OH)_2$ Dihydroxyammonia or nitroyl hydrate.	$N(OH)_3$ Ortho-nitrous acid.

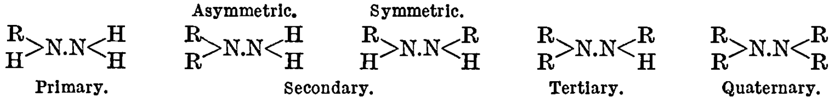
§ 26. Hydrazine or Diamide

The name **hydrazine** was applied by E. Fischer[1] in 1875 to the then hypothetical **diamide,** a kind of doubled ammonia, $H_2{=}N{-}N{=}H_2$, which he foresaw must be the parent of a series of substitution products in which the hydrocarbon radicles take the place of the hydrogen atoms. Twelve years earlier, A. W. Hofmann discovered the disubstituted symmetrical $(C_6H_5)H{=}N{-}N{=}H(C_6H_5)$, which he called **hydrazobenzene**; and in 1875, E. Fischer made the monosubstituted derivative, $(C_6H_5)H{=}N{-}N{=}H_2$, which he called **phenylhydrazine,** by treating aniline, $C_6H_5NH_2$, with nitrous acid so as to form **diazobenzene,** $C_6H_5N:N.OH$; and reducing the diazobenzene with stannous chloride and hydrochloric acid, so as to form the phenylhydrazine.

The four hydrogen atoms of the parent $H_2N.NH_2$ can be replaced by hydrocarbon radicles, R, in five different ways:



$$\begin{matrix}R\\H\end{matrix}\!>\!N.N\!<\!\begin{matrix}H\\H\end{matrix}\qquad\begin{matrix}R\\R\end{matrix}\!>\!N.N\!<\!\begin{matrix}H\\H\end{matrix}\qquad\begin{matrix}R\\H\end{matrix}\!>\!N.N\!<\!\begin{matrix}R\\H\end{matrix}\qquad\begin{matrix}R\\R\end{matrix}\!>\!N.N\!<\!\begin{matrix}R\\H\end{matrix}\qquad\begin{matrix}R\\R\end{matrix}\!>\!N.N\!<\!\begin{matrix}R\\R\end{matrix}$$

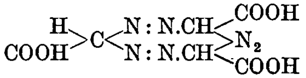
Asymmetric. Symmetric.

Primary. Secondary. Tertiary. Quaternary.

Representatives of all the five classes have been prepared, and the term hydrazine can be applied to all. H. Henstock gave for the electronic structure:

$$\begin{matrix}+H\\+H\end{matrix}\!>\!\bar{N}-\bar{N}\!<\!\begin{matrix}H+\\H+\end{matrix}$$

A. W. Hofmann's hydrazobenzene is symmetrical secondary hydrazine, or symmetrical diphenylhydrazine; and E. Fischer's phenylhydrazine is a primary compound. J. W. E. Glattfeld and C. H. Milligan made optically active hydrazines, *e.g.* dimethylpropylphenylhydrazine. The parent hydrazine was isolated in 1887, by T. Curtius, in the form of a hydrate and salts, by hydrolyzing **triazoacetic acid:**



$$\begin{matrix}H\\COOH\end{matrix}\!>\!C\!<\!\begin{matrix}N:N.CH\\N:N.CH\end{matrix}\!\begin{matrix}<COOH\\>N_2\\<COOH\end{matrix}$$

a compound, it will be observed, which contains the group —N : N— three times. Hydrazine has since been prepared from many other organic compounds containing paired nitrogen atoms; for instance, T. Curtius and R. Jay made it by the hydrolysis of amidoparaldimine, $C_6H_{12}O_2(N.NH_2)$; J. Thiele, by the hydrolysis of amidoguanidine, $NH_2.C(NH).NH.NH_2$; F. D. Chattaway, by the hydrolysis of paraurazide, $CO{=}(NH.NH)_2{=}CO$; W. Traube, by reducing methylenediisonitramine, $CH_2(N_2O_2)_2H_2$, with sodium amalgam; H. von Pechmann and P. Manck, by the hydrolysis of potassium sulphohydrazinomethylene disulphonate, $C(SO_3K)_2(NK)N.SO_3K.H_2O$; E. Buchner, by the hydrolysis of methyl furmaricdiazoacetate, $\{CH(COOCH_3)N\}_2CH.COOCH_3$, or ethyl cinnamicdiazoacetate, $(CHC_6H_5.N)\text{-}\{CH(COOH).N\}CH.COOC_2H_5$; and P. J. Schestakoff, by the action of sodium hypochlorite on urea: $NH_2.CO.NH_2+NaOCl=NH_2.C(ONa):NCl+H_2O$; followed by $NH_2.C(ONa):NCl=NH_2.N:CCl.ONa$; $NH_2.N:CCl.ONa+NaOH=NaCl+NH_2.NH.COONa$; and $NH_2.NH.COONa+H_2O=NaHCO_3+NH_2.NH_2$. F. Raschig said that a trace of hydrazine is formed in the oxidation of ammonia (*q.v.*). N. Tarugi said that in urine there is an oxydase which can split urca into carbon dioxide and hydrazine. The subject is discussed from the point of view of organic chemistry by N. V. Sidgwick, *The Organic Chemistry of Nitrogen* (Oxford, 1910); L. Spiegel, *Der Stickstoff und seine wichtigsten Verbindungen* (Braunschweig, 1902); H. Wieland, *Die Hydrazine* (Stuttgart, 1913); and H. Imbert, *De l'hydrazine et ses dérives* (Paris, 1899). The discovery and development of the different methods for preparing $NH_2.NH_2$ by organic chemists is an historical accident, for it can be prepared more simply from inorganic materials. H. S. Hirst, and W. A. Noyes detected traces of hydrazine and ammonia in the products of the action of nitrogen on hydrogen when exposed in silica tubes to ultra-violet light.

Hydrazine is a direct reduction product of hyponitrous acid. The presence of a sulphite is usually necessary for the reduction. Hydrazine does not usually appear as an intermediate stage in the formation of ammonia from nitric acid because, as shown by N. R. Dhar, it is more readily oxidized than ammonia by nitrous acid. P. Duden treated an alkaline soln. of potassium sulphite with nitrous oxide, and reduced the resulting potassium nitrosylsulphonate, $KSO_3.M(OK).NO$, with sodium amalgam in a conc. alkaline soln., at about 0°, in the presence of potassium hyponitrite and sulphite. The product is potassium hydrazine sulphite, $KSO_3.NH.NH_2$; formed by the reaction $KSO_3.N(KO).NO+3H_2 \rightarrow H_2O+KOH+KSO_3.NH.NH_2$. By acidifying and then warming the soln., hydrazine is set free. F. von Brackel obtained a very small yield of hydrazine by treating a soln. of hyponitrous acid with sodium hydrosulphite, evaporating the product in vacuo, and reducing it with zinc-dust and acetic acid. W. R. Hodgkinson and C. C. Trench also obtained a small yield by passing dry ammonia over heated and dry cupric sulphate. F. Raschig showed that a trace of hydrazine is formed in the limited oxidation of ammonia by oxygen: $4NH_3+O_2=2H_2O+2N_2H_4$; E. Divers and T. Haga, by the action of sodium amalgam on potassium nitrososulphate. A. Findlay noted the high tension brush discharge passing through a mixture of nitrogen and ammonia produces a little hydrazine. J. W. Turrentine and J. M. Olin found that the electrolysis of ammonium hydroxide in the presence of sodium chloride and glue, with a low current density furnishes hydrazine if the sodium chloride be added gradually in small quantities at a time during the electrolysis.

In 1907, F. Rashig showed that it is possible to make ammonia double itself, so to speak, by converting one part into chloramine, NH_2Cl, and bringing this into contact with more ammonia. The reaction is symbolized: $NH_3+NH_2Cl \rightarrow NH_2.NH_2.HCl$. This constructive reaction is opposed by the destructive changes $2NH_3+3NH_2Cl \rightarrow 3NH_4Cl+N_2$; and $2NH_2Cl+N_2H_4=2NH_4Cl+N_2$, which are favoured by decreasing the viscosity of the soln., say, by the addition of acetone, and it is retarded by the addition of substances, like glue or gelatin, which increase the viscosity of the soln. Hence, although the action of the glue or gelatin is not understood, the yield is much reduced if the colloid be absent. The reaction was studied by A. Stock.

Mix 200 c.c. of a 20 per cent. soln. of ammonia, 5 c.c. of a one per cent. soln. of glue or gelatine, and 100 c.c. of an aq. soln. of 7·5 grms. of sodium hypochlorite, free from an excess of chlorine—in a litre flask. Boil the mixture for about half an hour, when it will have evaporated to about half its original volume. Monochloramide is first formed, and this reacts with another mol. of ammonia to form hydrazine hydrochloride: $NH_2Cl+NH_3=N_2H_4.HCl$. When cold, place the flask in iced water, and add 20 c.c. of a soln. containing 1·96 grms. of sulphuric acid, H_2SO_4. Hydrazine sulphate crystallizes out. This may be purified by recrystallization from water. The process is used technically for the preparation of hydrazine sulphate.

N. Putochin, and B. P. Orelkin and co-workers used F. Raschig's method. R. A. Joyner studied the relation between the yield of hydrazine and the mol. ratio of ammonia to sodium hypochlorite and found the yield to be 5·7 per cent. when the ratio was 2·02; 32 per cent. with the ratio 8·8; and 75 per cent. with the ratio 76·8. With 0·400 mol of NH_3, 0·0100 mol of NaOCl in 110 c.c. of soln. and 0 mgrm. of gelatin, the yield was 2·0 per cent. of hydrazine; with 4·9 mgrms. of gelatin, the yield was 30·8 per cent.; and with 100·9 mgrms. of gelatin, the yield was 51 per cent. He found the yield was lowered by the addition of ammonium salts; it was scarcely affected by sodium sulphate or hydroxide, and was raised slightly by potassium chloride. The presence of hydrazine lowered the yield, showing that the opposing reaction is probably $2NH_2Cl+N_2H_4=2NH_4Cl+N_2$. Additions of gelatin, glue, and peptone had the same effect in raising the yield; starch, dextrine, and sucrose favoured the production of hydrazine, but only when present in amounts 100–300 times greater than that of gelatin. The effect of the sodium salts of glutamic acid, tyrosine, tryptophan, and uric acid was insignificant. Peptized silicic and stannic acids had strong catalyzing actions, the yield of hydrazine obtained with stannic acid being about equal to that produced by one-third the quantity of gelatin; with silicic acid, however, a yield equal to that obtained with glue could not be attained. The reaction was catalyzed by animal charcoal, wood charcoal, asbestos powder, and powdered meerschaum, when these were present in relatively large quantities. Kieselguhr, calcium phosphate, silica gel, French chalk, and kaolin had no action. There is no evidence of the formation of intermediate compounds between gelatin and chloroamine; and the acceleration of the reaction by glue may be due to a strong adsorption of the ammonia by the particles of glue, favouring the reaction $NH_2Cl+NH_3=N_2H_4.HCl$, and this also explains the favourable action of charcoal known to adsorb ammonia with avidity.

T. Curtius and H. Schulz prepared **hydrazine hydrate**, by distilling a mixture of hydrazine sulphate (100 grms.), potassium hydroxide (100 grms.), and water (250 grms.) in a silver retort provided with a silver condensing tube. The distillation was continued (5–6 hours) until the last drop had passed over, and the distillate (250 c.c.) was then fractionated, the fractions being best divided into below 101°, 101° to 104°, 104° to 117°, and 117° to the constant boiling temp. After four fractionations, the hydrazine hydrate (36 grms.) boiled constantly at 119°. C. A. Lobry de Bruyn avoided the use of the costly silver apparatus; he made the hydrate from commercial hydrazine sulphate by converting it into bromide by means of barium bromide, and this was then decomposed by the theoretical amount of aq. potash-lye. After the potassium bromide thus formed had been precipitated with alcohol, the alcoholic soln. of the hydrate was distilled under the ordinary press. until the temp. reached 108°, but little of the hydrate passing over below this point. Any further precipitate of potassium bromide having been removed, the liquid is fractionated first under atm. press. until the temp. reached 118°, and then under a press. of 121–125 mm., the fraction boiling at 73° contained 99·7 per cent. of hydrazine hydrate, and was free from silica. The yield, however, was only 22 per cent. of that required by theory. The barium salt can be dispensed with, and simple fractionation employed.

C. A. Lobry de Bruyn obtained nearly pure **anhydrous hydrazine** as a viscous liquid by distilling, under reduced press., a mixture of hydrazine hydrate and barium oxide prepared in a flask cooled by a freezing mixture. He obtained 92 per cent. hydrazine by boiling the hydrochloride with sodium methoxide for half an hour, $N_2H_4.HCl+NaOCH_3 \rightarrow NaCl+CH_3OH+N_2H_4$. After removing the sodium chloride, the liquid was distilled under reduced press. The first distillation gave 73 per cent. hydrazine; the second, 82–84 per cent.; and this after fractional crystallization gave a product with 92 per cent. hydrazine. Contact with rubber must be avoided. The product can be preserved in sealed glass tubes from which air has been displaced by hydrogen. C. F. Hale and F. F. Shetterly have studied the preparation of anhydrous hydrazine with barium oxide, barium hydroxide, and sodium hydroxide as dehydrating agents. Barium oxide gave the best results. E. Ebler and R. L. Krause also used barium oxide. A. Stähler used calcium oxide, and F. Raschig, sodium hydroxide. R. Stollé and K. Hofmann distilled hydrazine carboxylic acid, $NH_2.NHCOOH$, over calcium or barium oxide; A. Djawachoff heated hydrazine borate, $(N_2H_4)_2(B_2O_3)_6$, to 270° and obtained anhydrous hydrazine; and R. Stollé treated sodium amide with an excess of hydrazine hydrate: $N_2H_4.H_2O+NaNH_2=N_2H_4+NH_3+NaOH$. If the sodium amide be in excess the reaction was symbolized: $N_2H_4+NaNH_2=NH_3+NaN_2H_3$. T. Curtius and

F. Schrader said that pure hydrazine can be preserved in a sealed tube without alteration, but the dil. soln. rapidly loses its characteristic properties.

The physical properties of hydrazine and its hydrate.—Anhydrous hydrazine is a colourless, corrosive liquid which fumes strongly in air, and hydrazine hydrate may be described in the very same words. C. A. Lobry de Bruyn gave 1·014 for the sp. gr. of the hydrazine at 15°/15°, and 1·008 at 23°/15°; while J. W. Brühl gave 1·0256 at 0·2°/4°, and 1·0258 at 0°/4°. T. Curtius and H. Schulz gave 1·03 to 1·0305 for the sp. gr. of hydrazine hydrate at 21°. J. W. Dito found 1·0114 for the sp. gr. of hydrazine at 15°/4°, and as water is added, the sp. gr. rises to a maximum 1·0470 with 64·1 per cent. N_2H_4 corresponding with $N_2H_4.H_2O$; and with more water, the sp. gr. falls continuously. K. Jablczynsky measured the vol. of hydrazine ions. T. Curtius and H. Schulz found the vap. density of the hydrate at 100° in vacuo corresponded with the formula $N_2H_4.H_2O$; at 170°, with the complete dissociation $N_2H_4.H_2O \rightleftharpoons N_2H_4+H_2O$; and above 170°, the hydrazine breaks down. According to A. Scott, at 98·8°, the vap. density is 15·8 corresponding with $N_2H_4.H_2O$; the dissociation of the hydrate is complete, and above that temp. ammonia and nitrogen are formed. A. P. Sabanéeff found that some hydrazoic acid is formed when the hydrazine nitrates are decomposed by heat; and J. W. Turrentine showed that azoimide is produced by the decomposition of hydrazine nitrate and dinitrate. The decomposition of some other hydrazine salts has now been studied. F. Balla found practically all the current was consumed in the oxidation $N_2H_4+O_2=N_2+2H_2O$. C. A. Lobry de Bruyn found the b.p. of hydrazine to be 56° at 71 mm.; 113·5° at 761·5 mm.; and 134·6° at 1490 mm.; while the hydrate boils at 46° at 26 mm., and at 118·5° at 739·5 mm. The critical temp. of hydrazine is 380°, and the critical press., 145 atm. Hydrazine is decomposed $3N_2H_4=N_2+4NH_3$ above 350°. Hydrazine freezes at 0°, and its m.p. is 1·4°—there is much undercooling. F. Friedrichs gave 1·8° for the m.p. of hydrazine. T. Curtius and co-workers found that when the hydrate is strongly cooled, it furnishes crystalline plates which melt at —40°. The determination of the f.p. enables the mol. wt. of hydrazine in water to be calculated, and the result 68 is in agreement with the formula $N_2H_4.2H_2O$. C. A. Lobry de Bruyn found the b.p. of mixtures of hydrazine and water has a maximum at 120·5°, 771 mm. press., for a mixture with 58·5 per cent. of N_2H_4, and 41·5 per cent. of water.

M. Berthelot and C. Matignon found the heat of formation to be $(N_2,H_4,Aq.)=N_2H_{4soln.}-9{\cdot}5$ Cals.; hydrazine is an endothermal compound, and its conversion into ammonia liberates 51·5 Cals., and the reaction is not reversible. $N_2H_4.Aq.=NH_3.Aq.+N+H+25{\cdot}75$ Cals.; $3N_2H_4Aq.=4NH_3Aq.+N_2+98{\cdot}25$ Cals.; and $N_2H_4.Aq.+H_2=2NH_3Aq.+51{\cdot}5$ Cals. R. Bach gave for the formation of various combinations, $(N_2H_5OH,Aq.)=19{\cdot}19$ Cals.; $(N_2H_5.HSO_4,Aq.)=-85{\cdot}27$ Cals.; $(N_2H_5Cl,Aq.)=-54{\cdot}40$ Cals.; $(N_2H_5Cl.HCl,Aq.)=-62{\cdot}01$ Cals.; $(N_2H_5OHAq.,H_2SO_4Aq.)=113{\cdot}0$ Cals.; $(N_2H_5OHAq.,2HClAq.)=96{\cdot}0$ Cals.; $(N_2H_5OHAq.,HClAq.)=96{\cdot}5$ Cals.; $(N_2H_5OHAq.,2HNO_3Aq.)=97{\cdot}0$ Cals.; $(N_2H_5OHAq.,HNO_3Aq.)=97{\cdot}0$ Cals.; and for the heat of formation of hydrazine hydrate, $(N_23H_2,O)=561-644$ Cals. The fact that the heat of formation is a positive quantity shows that hydrazine hydrate is probably not the analogue of the diazo-compounds, but rather has the constitution $H_2N.NH_3.OH$, and not $H_3N.NH_2.OH$. The observed data just indicated shows that the hydrazine salts $N_2H_4.HR$ are not converted into $N_2H_4.2HR$ salts in aq. soln. since the heats of neutralization of hydrazine hydrate by either one or two eq. of the acid are the same. From this, it is probable that the salts $N_2H_4.2HR$ undergo hydrolytic dissociation in aq. soln., and this, taken in conjunction with the electrolytic dissociation which takes place at the same time, would explain the fact that the mol. wt. of these salts as determined by the cryoscopic method are only one-fourth of those expressed by their formulæ. J. Thomsen has discussed the thermochemistry of hydrazine. The heat of neutralization is less than that of ammonia, or hydroxylamine.

J. W. Brühl gave 8·867 for the mol. refraction, with the μ^2 formula (**1**, 11, 13) for Na-light, and for H_α-light, 8·82; and for the mol. dispersion, $M(\gamma-\alpha)=0·266$. According to R. Bach, the mol. refractions of hydrazine hydrate show that the at. refraction of nitrogen deduced from the mol. refraction of the hydrate is much smaller than the value obtained from the other hydrazine salts and other nitrogen compounds. The value for the two nitrogen atoms calculated for the formula $(n-1)/d$ is 9·5 in the case of the hydrate, and nearly 11 for the salts. In this behaviour, hydrazine resembles ammonia, as the latter aq. soln. also gives a very much smaller value for the at. refraction of nitrogen than that deduced from the ammonium salts or the amines.

E. C. Szarvasy found that on electrolysis of soln. of hydrazine hydrate, sulphate, or chloride, nitrogen and hydrogen were produced in quantities corresponding with the quantitative decomposition of the base; and J. W. Turrentine and coworkers found that with a high current density, and low temp., and strongly acid salt soln. of hydrazine sulphate furnished hydrazoic acid, and its formation was attributed to the persulphate-ions; in the case of hydrazine carbonate, under conditions which would favour the formation of percarbonates, the hydrazine suffered quantitative oxidation into nitrogen and water. In the electrochemical oxidation of hydrazine hydrochloride and hydrobromide, hydrazoic acid was not obtained under any conditions. At low temp. and with low current densities only nitrogen and water were produced, whilst at high temp. and with high current densities considerable quantities of ammonia were formed. In certain experiments with the hydrochloride, the conditions were such as should have led to the formation of chlorate ions. The production of chlorate seemed, however, to be rendered impossible owing to the reduction of the hypochlorite by the hydrazine present. S. Bodforss studied the electrolysis of soln. of hydrazine sulphate. E. Cohen and C. A. Lobry de Bruyn found for the smallest electrical conductivity of anhydrous hydrazine halides, 4×10^{-5} mho. The addition of ammonia increases the conductivity only slightly; and with water additions, the conductivity of hydrazine falls to a minimum with 60 molar proportions of water to 100 of hydrazine. G. Bredig gave for the mol. conductivity, μ, for a mol of the hydrate, $OH_4N.NH_3(OH)$, in v litres of water, at 25°:

v .	8	16	32	64	128	256	8	
μ .	1·33	1·56	1·93	2·53	3·57	5·14	224	
α .	0·594	0·70	0·86	1·13	1·59	2·30	—	per cent.
K_1 .	$0·0_544$	$0·0_530$	$0·0_523$	$0·0_521$	$0·0_520$	$0·0_521$	—	

The percentage degree of ionization, α; and the ionization constant K_1 are also indicated. Hence, the first ionization constant is rather weaker than that of ammonium hydroxide, being somewhere near $K_1=3\times10^{-6}$. I. M. Kolthoff calculated for the second ionization constant of hydrazine, $K_2=2·8\times10^{-3}$; and E. C. Gilbert said that it should be less than 10^{-12}. P. Drude gave 53 for the dielectric constant at 22°.

The chemical properties of hydrazine and its hydrates.—O. Löw found that hydrazine exerts an extremely poisonous action on organisms—seedlings, fungi, and infusoriæ. A subcutaneous injection of 0·1 mgrm. of hydrazine sulphate, neutralized with sodium carbonate, in a guinea-pig caused death in 2½ hrs.; and 0·5 grm. administered to a puppy, similarly, caused death in 2½ hrs. P. Borisoff reported that when subcutaneously injected in dogs, small doses (0·05 grm. of the hydrazine sulphate per kilo. of body weight) acted as a slight stimulant; and with large doses (0·1 grm. per kilo.) the stage of stimulation was more intense, and followed by depression, ending in coma and death in two days. Given by the mouth, it produced salivation and sickness. The heart went more quickly at first, then slowed gradually and became irregular. The respiratory movements reminded one of asthma. The temperature of the body sinks. The urine was strongly acid, and contained small quantities of the unchanged hydrazine, a small amount of albumin, in one case bile pigment, and in most cases considerable quantities of allantoin. The saliva, which is abundant, also contained allantoin. Observations on the subject were also made by F. P. Underhill and co-workers. M. Raciborsky showed that some fungi can assimilate hydrazine. Both hydrazine and its hydrate absorb moisture and carbon dioxide from **air.** Hydrazine is slowly attacked by **oxygen** with the liberation of nitrogen, and it burns with a blue flame in air; hydrazine hydrate slowly oxidizes in air with the liberation of nitrogen. F. D. Chattaway discussed the oxidation of aromatic hydrazines by air or free oxygen. E. J. Cuy and W. C. Bray said that the presence of oxygen is responsible for the fairly rapid decomposition of hydrazine in alkaline soln. Hydrazine and its hydrate are miscible with **water** in all proportions. K. Neundlinger studied the catalysis of hydrazine by platinum-black—*vide infra.* A. W. Browne and F. F. Shetterly found that **ozone** may react with hydrazine, forming hydrazoic acid, but no ammonia. W. Strecker and H. Theinemann observed that hydrazine hydrate is oxidized by ozone principally to nitrogen and water, only small quantities of ammonium and hydrazine nitrates being formed. A. W. Browne found that **hydrogen dioxide** in dil. sulphuric acid soln. forms a little hydrazoic acid when in the presence of a soln. of hydrazine: $3N_2H_4+5H_2O_2=2HN_3+10H_2O$. A. W. Browne and O. R. Overman found that the presence of ammonium sulphate does not increase, but rather decreases, the yield of hydrazoic acid when hydrazine sulphate is oxidized by hydrogen dioxide in sulphuric acid soln. C. Wurster found that phenylhydrazine is converted by hydrogen dioxide into benzene and diazobenzene imide. The production of benzene makes it probable that free diazobenzene is first formed in the oxidation of the hydrazine.

Hydrazine and its combinations are very powerful reducing agents. Some **oxidizing agents** oxidize aq. soln. of hydrazine to ammonia, NH_3, with the formation of but little hydrazoic acid, N_3H; and the other oxidizing agents give comparatively large yields of the acid and but little ammonia. According to C. A. Lobry de Bruyn, hydrazine inflames when in contact with **chlorine**; and with **bromine** and **iodine,** the corresponding haloid acids are produced, and nitrogen is set free. C. T. Dowell showed that nitrogen trichloride is probably formed when chlorine acts on hydrazine in contact with carbon tetrachloride. T. W. B. Welsh and H. J. Broderson found that iodine is very soluble in anhydrous hydrazine, and causes a rapid decomposition. With chlorine, a small amount of hydrazoic acid is formed in both acid and alkaline soln.; with bromine, mere traces in alkaline and none in acid soln.; and with iodine, no hydrazoic acid was observed. Alcoholic soln. of hydrazine hydrate and iodine react quantitatively: $5N_2H_4.H_2O+2I_2 \rightarrow 4N_2H_4.HI+N_2+5H_2O$, and hence the reaction could be utilized in finding the strength of soln. of hydrazine. Chlorine water and hydrazine sulphate react: $N_2H_4+2Cl_2=4HCl+N_2$, and hence, hydrazine sulphate can be utilized in the analysis of chloride of lime and Javelle water. The reaction with iodine was studied by E. Rupp, and R. Stollé from the point of view of volumetric analysis; and E. C. Gilbert studied the electrometric titration. Hydrazine hydrate reacts with **acids** to form salts—*vide infra,* hydrazine halides. E. Riegler studied the reduction of *iodic acid* by hydrazine sulphate; R. Stollé, E. Rupp, and H. Spiess showed that a soln. of iodine in the presence of sodium or potassium hydrocarbonate acts on hydrazine and its salts: $N_2H_4+2I_2=4HI+N_2$. F. W. O. de Coninck found that with **alkali hypochlorites,** there is a copious evolution of nitrogen. G. R. Levi represented the reaction with alkali **chlorites:** $N_2H_4.2HCl+NaClO_2=N_2+NaCl+2H_2O+2HCl$, though he prepared hydrazine chlorite by double decomposition. According to A. W. Browne and F. F. Shetterly, and W. R. Hodgkinson, **chlorates, bromates,** and **iodates** are not reduced by hydrazine, unless in the presence of small amounts of silver sulphate, metallic copper, copper oxide, or a copper salt. K. A. Hofmann observed that a neutral or slightly acid soln. of potassium chlorate in the presence of a trace of osmium tetroxide readily decomposes hydrazine sulphate to nitrogen, etc. A. W. Browne and F. F. Shetterly, and W. R. Hodgkinson noticed that other metals which change easily from an -ic to -ous condition also act catalytically: $2KClO_3+3N_2H_4 \rightarrow 6H_2O+3N_2+2KCl$. The reaction is rapid in acid soln., but very slow in neutral or alkaline soln. The reaction has been recommended for estimating the total chlorine, bromine, or iodine in the respcctive chlorates, bromates, or iodates—the excess of hydrazine can be destroyed by permanganate soln. acidified with nitric acid. The reaction between hydrazine sulphate and potassium iodate, $5N_2H_4.H_2SO_4+4KIO_3 \rightarrow 5N_2+12H_2O+2K_2SO_4+3H_2SO_4+2I_2$, has been recommended by E. Rimini for the determination of hydrazine; but the reaction with the chlorates and bromates is not quantitative. T. Curtius and H. Schulz, M. Schlötter, P. Jannasch and A. Jahn, F. Fischer and W. F. Tschudin, and A. Kurtenacker and J. Wagner, studied the oxidation of hydrazine by bromates; and E. C. Gilbert, the electrometric titration of hydrazine with potassium bromate. A. W. Browne and F. F. Shetterly found that hydrazine is in part converted to hydrazoic acid by **potassium perchlorate,** and by **sodium periodate.** W. R. Hodgkinson said that perchlorates are not reduced in the same way as the chlorates; hydrazine nitrate and **ammonium perchlorate** may be fused together without reacting.

T. Curtius and co-workers, and T. W. B. Welsh and H. J. Broderson found that hydrazine or its hydrate slowly dissolves **sulphur** with the development of much heat, and the formation of a brown liquid which smells like ammonium sulphide and deposits sulphur when treated with water. A 23 per cent. aq. soln. of hydrazine, when boiled with sulphur, gives off hydrogen sulphide. F. Ephraim and H. Piotrowsky found that the reaction in a short time is $N_2H_4+2S=N_2+2H_2S$. H. Piotrowsky represented the reaction $N_2H_4+2S=N_2+2H_2S$, and a side reaction, $2N_2H_4+S=N_2+2NH_3+H_2S$, **hydrogen sulphide** readily dissolves in hydrazine hydrate, but no solid is produced; with anhydrous hydrazine, H. Piotrowsky believes that hydrazine hydrosulphide, $2N_2H_4.H_2S$, is formed with a dissociation press. of 760 mm. at 35°. H. Piotrowsky represented the reaction with **thionyl chloride,** $SOCl_2+4N_2H_4=SO(NH.NH_2)_2+2N_2H_5Cl$; the reaction with **sulphur dioxide** results in the formation of **hydrazine disulphinic acid,** $SO_2H.NH.NH.SO_2H$, which forms salts, $(HN.SO_2)_2Ba$ and $Ba(N.SO_2)_2Ba$; and with **sulphur trioxide,** there is formed sulphur dioxide, sulphur, and sulphur sesquioxide, S_2O_3. With **sulphur dioxide,** hydrazine forms the hydrazine salt of an unknown acid, **hydrazine disulphuric acid,** $SO_2H.NH.NH.HSO_2$, by direct addition: $2SO_2+3N_2H_4=N_2H_2(HSO_2.N_2H_4)_2$; **thionyl chloride** is reduced to sulphur, which dissolves in the excess of hydrazine, forming **sulphohydrazinium.** H. T. Bucherer and co-workers studied the action of **sulphites** on the hydrazines. Anhydrous hydrazine absorbs **sulphur trioxide** when exposed to the vapour of this compound diluted with much air, and **hydrazine sulphonic acid,** $N_2H_3.HSO_3$, is formed. Barium and calcium salts have been prepared directly from the acid, while the alkali, silver, and ammonium salts are obtained by double decomposition with the former. If hydrazine sulphonic acid be powdered and mixed in small portions at a time with a well-cooled soln. of potassium nitrate, flat prisms of the potassium salt of **azidosulphonic acid,** N_3SO_3H, are formed. The crystals explode when heated, and the aq. soln. is decomposed into hydrazoic acid, N_3H, and sulphuric acid when treated with mineral acids. Hydrazine reduces **sulphuric acid** to hydrogen sulphide—*vide infra,* hydrazine sulphates. A. W. Browne and F. F. Shetterly found that hydrazine is partly oxidized to hydrazoic acid by **persulphates,** and partly to nitrogen, according to E. Pannain: $2K_2S_2O_8+N_2H_4.H_2SO_4+6KOH=5K_2SO_4+N_2+6H_2O$. E. Rimini gave: $N_2H_4.KHSO_4+5KOH+2K_2S_2O_8=N_2+5K_2SO_4+5H_2O$. W. R. Hodgkinson made some observations on this subject. A. W. Browne and F. F. Shetterly found that hydrazine gives no hydrazoic acid with **selenious acid,** but **selenic acid** gives an appreciable quantity; and **telluric acid** gives much hydrazoic acid and ammonia.

According to A. W. Browne and co-workers (T. W. B. Welsh, and A. W. Browne and A. E. Houlehan), the amminolysis of hydrazine sulphate or selenate occurs when the salt is treated with liquid **ammonia:** $N_2H_4.H_2SO_4+2NH_3=(NH_4)_2SO_4+N_2H_4$. F. Friedrichs found the reaction is quantitative, and he was not able to detect any sign of chemical combination between ammonia and hydrazine. His measurements of the temp., θ; vap. press., p mm. of the sat. soln.; and of the conc., C, of the sat. soln. with solid hydrazine in equilibrium with the ammonia; and the conc., C_1, of the sat. soln. with solid ammonia in equilibrium are shown in Table XXIX,

TABLE XXIX.—PRESSURE, TEMPERATURE, AND CONCENTRATION RELATIONS OF THE BINARY SYSTEM: NH_3–N_2H_4

where the conc. are expressed in percentages of ammonia. Hydrazine dissolves ammonia gas. R. Stollé found that **sodamide** with an excess of hydrazine hydrate reacts: $N_2H_4.H_2O+NH_2Na=N_2H_4+NH_3+NaOH$; and if the sodamide be in excess, **sodium hydrazine** is formed: $N_2H_4+NaNH_2=NH_3+NaN_2H_3$. According to K. A. Hofmann and R. Kroll, hydrazine hydrochloride decomposes at 200° into ammonium and hydrogen chlorides and nitrogen in the presence of **hydroxylamine hydrochloride,** a reaction occurs at about 150° and, with suitable proportions of the reactants, follows the course: $2NH_2.OH+N_2H_4.2HCl=2NH_4Cl+N_2+2H_2O$. The absence of nitrous oxide from the products indicates the quantitative participation of hydroxylamine in the change and the probable preliminary formation of a very unstable salt of diaminohydrazine. E. Ebler and R. L. Krause obtained a product which explodes at 70°, by the action of ethereal soln. of hydrazine on **zinc diamide,** or by the action of **zinc ethyl** and hydrazine. The composition is ZnN_2H_2, or **zinc hydrazine.** T. Curtius observed that hydrazine hydrate reacts vigorously with **nitrous acid** and the *nitrites*, forming, under some conditions, hydrazoic acid (*q.v.*), under others hydrazine nitrite (*q.v.*). The reaction was studied by J. de Girard and A. de Saporta, B. B. Dey and H. K. Sen, and F. Sommer. C. A. Lobry de Bruyn found that **nitrous oxide** reacts with hydrazine. J. de Girard and A. de Saporta symbolized the reaction $N_2H_4.H_2SO_4+2NaNO_3=N_2+Na_2SO_4+2HNO_2+2H_2O$; but E. Francke prefers, $N_2H_4+HNO_2=N_2O+NH_3+H_2O$. The mechanism of the reaction was studied by F. Sommer and H. Pincas, A. W. Browne and O. R. Overman, F. Sommer, A. Angeli, E. Oliveri-Mandala, E. Francke, T. Curtius, M. Dennstedt and W. Göhlich, etc. The action of nitrites was studied by B. B. Dey and H. K. Sen; and the action of nitrous esters, by M. Betti, R. Stollé and J. Thiele. Larger yields of hydrazoic acid and smaller yields of ammonia were obtained by A. W. Browne and O. R. Overman during the oxidation of hydrazine sulphate by potassium nitrate than in the case with hydrogen dioxide. For the action of **nitric acid,** *vide* hydrazine nitrate. White **phosphorus** reacts with hydrazine or its hydrate, and the soln. becomes yellow, reddish-violet, and black; the smell of phosphine is then perceptible. When the black liquid is diluted with water, a black precipitate is formed, which C. A. Lobry de Bruyn considered to be a solid phosphorus hydride. The reaction was studied by J. W. Dito. For the action of **phosphoric acid,** see hydrazine phosphates. A. W. Browne and F. F. Shetterly found that **arsenious oxide** with hydrazine gives hydrazoic acid and ammonia. W. R. Hodgkinson studied the action of **arsenates** on hydrazine. C. A. Lobry de Bruyn found that hydrazine and its hydrate react with **carbon dioxide**; and there is a vigorous reaction with **carbonyl chloride.** Hydrazine and its hydrate are soluble in **methyl, ethyl, propyl, butyl, and amyl alcohols,** but they are not soluble, or only slightly soluble in the usual organic solvents. W. Schlenk and T. Weichselfelder found that hydrazine reacts with methyl alcohol, and the soln., on cooling, furnishes colourless leaflets of **hydrazine methyl alcoholate,** $(NH_2.NH_3)OCH_3$, isomeric with methylhydrazine hydrate, $(NH_2.NH_2CH_3)OH$. A. Angeli found that the action of **cyanogen** on hydrazine produces a substance with the composition $C_2N_6H_8$. G. Pellizzari and co-workers found that with **cyanogen chloride or bromide,** hydrazine in aq. soln. furnishes diaminoguanidine, $NH : C(NH.NH_2)_2$. E. J. Cuy and W. C. Bray found that in alkaline soln., hydrazine is quantitatively oxidized to nitrogen by **potassium ferrocyanide,** R. von Rothenburg found that **chloroform** is not acted on in boiling soln., while **iodoform** is slightly attacked.

J. Houben obtained methane, etc., by the action of *magnesium alkyl haloids* on the hydrazines; the action of *zinc ethyl* and magnesium alkyl haloids on hydrazine has been studied by R. L. Krause; the action of mono- and di- *chloroacetic acids,* by M. Busch and E. Meussdörffer; *ethyl chloroacetate,* by A. Reissert and W. Kayser, and M. Busch and co-workers; *phenylglyoxalic acid,* by A. Elbers; *dinitrophenylhydrazine,* by T. Curtius and M. Mayer; *ethyl dinitrobenzoate,* by T. Curtius and A. Riedel; *dinitrobenzoic acid,* by T. Curtius and H. F. Bollenbach; *nitro- and amido-phthalhydrazides,* by T. Curtius and A. Hoesch; *formaldehyde,* by E. Riegler, and E. Rimini; *carbonyl* compounds, by H. Standinger and O. Kupfer; *dicyanodiamide,* by K. A. Hofmann and O. Ehrard; *fats,* by P. Falciola and A. Mannino; *nitriles,* by E. Müller and L. Herrdegen, W. F. Donath, I. Lifschitz, and T. Curtius and co-workers; *chloral hydrate* and *bromal hydrate,* by G. Knöpfer; *nitroso-bases,* by O. Fischer and co-workers, and R. von Rothenburg; *chloroketones,* by S. Bodforss; *imido-ethers,* by A. Pinner; *thiamides,* by A. Junghahn and co-workers; *ethylene bromide,* by R. Stollé; *thiocarbamides,* by M. Busch and co-workers; *oxalacetic acid,* by H. J. H. Fenton and H. O. Jones; *acetonyl acetone,* by T. Gray; *methyl butyrylacetoacetates,* by A. Bongert; *methylethylacraldehyde,* by F. Demmer; *lactones,* by J. Wedel; *acetic anhydrides,* by R. Stollé; *chloro- and bromo-anilic acids,* by A. Descomps; *phenols,* by L. Hoffmann; *acetamide,* by M. O. Forster; *nitrodiazobenzene,* by H. von Pechmann; *picrylic chloride,* by A. Purgotti; *benzoic chloride, methyl iodide, ethyl iodide,* and *isoamyl chloride,* by R. von Rothenburg; *metaphosphoric and phosphorous esters,* by W. Strecker and H. Heuser; etc.

Hydrazine attacks *indiarubber,* and *cork;* and, when boiled in aq. soln., *glass* is eroded. Hydrazine hydrate and **sodium** develop much heat, with the expulsion of hydrogen and ammonia. When the liquid cools, a crystalline substance is formed which is soluble in water and alcohol, and which is thought to be *sodium hydrazide hydroxide,* N_2H_5ONa. The aq. soln. gives the reactions for hydrazine. T. Weichselfelder prepared the derivatives:

$\begin{matrix}CH_3\\Na\end{matrix}>N.N<\begin{matrix}H\\H\end{matrix}$

$\begin{matrix}CH_3\\C_6H_5\end{matrix}>N.N<\begin{matrix}H\\Na\end{matrix}$

$\begin{matrix}C_6H_5\\C_6H_5\end{matrix}>N.N<\begin{matrix}H\\Na\end{matrix}$

$\begin{matrix}C_6H_5\\Na\end{matrix}>N.N<\begin{matrix}C_6H_5\\Na\end{matrix}$

According to E. Scandola, when hydrazine is added drop by drop to finely granulated sodium suspended in ether, and then heated on a water-bath with a reflux condenser, a white substance is formed which explodes in air. If left in contact with the ether, it loses its explosive property. The white compound does not act on silver nitrate in ammoniacal soln. Its structure is supposed to correspond with *sodium triimide* or **sodium hydrazide :**

$\begin{matrix}Na.N\\Na.N\end{matrix}>N—H, \text{ or } \begin{matrix}H.N\\H.N\end{matrix}>N—Na$

This substance was studied by T. W. B. Welsh, who found that the electrolysis of soln. of sodium hydrazide in anhydrous hydrazine furnishes nitrogen and hydrogen at both the anode and cathode. For each atom of copper deposited on the coulometer cathode, 1·1–1·5 atoms of nitrogen were liberated at the anode when the soln. were fairly dil., but in the case of more conc. soln. the ratio Cu : N was lower, and had an average value of 1 : 2·4. Sodium hydrazine, $NH_2.NHNa$, was obtained in glistening leaflets by W. Schlenk and T. Weichselfelder. "A mere breath of air or a trace of moisture or alcohol sufficed to produce a disastrous explosion." E. Ebler and E. Schott found that **zinc** partly immersed in hydrazine hydrate while exposed to air, furnishes white crystalline *zinc hydrazinecarboxylate dihydrazinate*, $(NH_2.NH.CO.O)_2{=}Zn{=}(NH_2.NH_2)_2$, and hydrogen is evolved. In the presence of **platinum**, aq. soln. of hydrazine are catalytically decomposed: $2N_2H_4 = 2NH_3 + N_2 + H_2$. S. M. Tanatar found that if sodium hydroxide be present, the reaction is to be symbolized: $3N_2H_4 = 2NH_3 + 2N_2 + 3H_2$; and if sulphates be present, $3N_2H_4 = 4NH_3 + N_2$. A. Gutbier and K. Neundlinger found no evidence of the formation of hydrogen or of nitrous oxide; hydrogen is formed in the presence of barium hydroxide and alkali hydroxides. They thus explain the reaction: the hydrazine breaks up into hydrogen and nitrogen in the presence of platinum black; the nascent hydrogen then reduces two mols. of hydrazine to ammonia. Should, however, the dissociation of the hydrazine hydrate be prevented by the presence of a strong base, the reducing action of the nascent hydrogen is retarded, and consequently free hydrogen is liberated. The velocity of the decomposition of hydrazine is proportional to the quantity of the catalyst present, and is uninfluenced by glass. The hydrazine can only be decomposed to the extent of 93 per cent. The order of reaction could not be determined, but is shown to depend on the condition of the platinum-black. A. Purgotti and L. Zanichelli showed that a soln. of hydrazine sulphate is not decomposed catalytically if the platinum-black has been boiled in water for four hours. This fact makes it appear as if it is the occluded oxygen which induces the catalytic process, and this inference is confirmed by the restoration of the activity of the platinum black if it be dried in air. Immersion in hydrogen dioxide does not restore its activity. Platinum black which is inactive towards hydrazine may still stimulate the decomposition of hydrogen dioxide and hydroxylamine, showing that the mechanism of the reaction is probably different. A. Purgotti and L. Zanichelli found that the velocity of decomposition increases nearly proportionately to the increase in the amount of platinum present, and roughly also to the increase of conc. The rate of decomposition by platinum of aq. salts of hydrazine varies greatly with the nature of the acid; the monohydrochloride, sulphate, nitrate, and hydrobromide are most rapidly affected and in the order given, whilst the diacetate, dihydrochloride, and dihydrobromide are much less readily decomposed. The addition of traces of acids has a very varying influence on the catalysis; sulphuric, hydrochloric, phosphoric, and boric acids have little effect, but hydrofluoric, hydrobromic, hydriodic, and nearly all organic acids very much retard, if they do not completely inhibit, decomposition. These facts explain the varying nature of the catalysis of hydrazine salts in soln. A. P. Sabanéeff found that if oxygen be passed into a soln. of hydrazine sulphate in which platinum-black is suspended, the following reaction occurs in the course of one or two hours: $4N_2H_4.H_2SO_4 + 5O = 3N_2 + 5H_2O + 3H_2SO_4 + (NH_4)_2SO_4$. K. Neundlinger studied this subject.

Anhydrous hydrazine dissolves many **salts**, thus, 100 parts of solvent at 12·5°–13° dissolve 12·2 parts of *sodium chloride;* 8·5, of *potassium chloride;* 56·4, of *potassium bromide;* 135·7, of *potassium iodide;* 26·6, of *sodium nitrate;* 21·7, of *potassium nitrate;* and 81·1, of *barium nitrate.* The hydrazine seemed to unite with sodium chloride; with a warm soln. of *ammonium chloride,* ammonia is evolved, and in the cold, there seems to be a state of equilibrium; a complex salt seems to be formed with *lead nitrate.* An aq. soln. of hydrazine hydrate also dissolves a number of salts, potassium bromide and iodide, *ammonium sulphate, potassium cyanide,* barium nitrate, *magnesium sulphate,* etc. According to T. W. B. Welsh and H. J. Broderson, the solubility of the metal haloids seems to increase with the increase of at. wt. of the halogen; in the case of the haloids of the alkali earth metals, crystalline substances separate from the soln., which are probably hydrazinated salts. The carbonates are either insoluble or very slightly soluble. The oxides are all insoluble. The nitrates are mostly soluble, with the exception of those which react with the solvent. Sulphides and sulphates are but slightly soluble. Ammonium salts, except triammonium phosphate, dissolve with evolution of ammonia. Bismuth chloride dissolves, and reacts with the hydrazine, bismuth being quantitatively precipitated. Cadmium carbonate and sulphide are insoluble, but the haloids are very soluble. Mercury sulphide is insoluble, but the other mercury salts react immediately with the solvent, and mercury is precipitated. Nickel and cobalt salts dissolve, and react with the solvent to form hydrazine additive compounds. In the case of cobalt chloride, a cobalt mirror is gradually formed. Copper and lead salts dissolve with more or less decomposition. Silver salts invariably yield a silver mirror.

A great many salts are reduced by hydrazine and its salts; thus, T. Curtius found that neutral copper sulphate, and Fehling's soln. give a dense, red precipitate. According to A. W. Browne and F. F. Shetterly, the azure-blue soln. of a copper salt containing an excess of ammonia, is rapidly decolorized by warming it with hydroxylamine or hydrazine salts owing to the reduction of ammino-cupric sulphate, $Cu(NH_3)_4SO_4$, to ammino-cuprous sulphate, $Cu_2(NH_3)_4SO_4$, with the evolution of nitrogen gas: $4Cu(NH_3)_4SO_4+N_2H_4H_2SO_4 \rightarrow 2Cu_2(NH_3)_4SO_4 +3(NH_4)_2SO_4+2NH_3+N_2$. The colourless soln., in the absence of an excess of reducing agent, is gradually coloured blue by exposure to air or by treatment with an oxidizing agent—*e.g.* hydrogen peroxide. If the colourless soln. be acidified and treated with potassium iodide or potassium thiocyanate, colourless cuprous iodide or thiocyanate is respectively precipitated directly. A. Purgotti represented the reaction in a boiling soln. of hydrazine and copper sulphates, and sodium chloride, $4CuSO_4+10NaCl+N_2H_4.H_2SO_4=4CuCl+5Na_2SO_4+6HCl+N_2$. T. Curtius found that when hydrazine is added to a soln. of ammoniacal **silver nitrate,** a precipitate of metallic silver is formed; and with an acid soln. of **gold chloride,** the metal is deposited. The reaction was studied by F. Schrader. The dehydrating action of **sodium hydroxide,** and of **barium oxide or hydroxide,** has been discussed in connection with the preparation of anhydrous hydrazine. A. Stähler suggested that **calcium oxide or hydroxide** forms either a solid soln. or a **calcium oxyhydrazide,** $Ca(ON_2H_5)_2$, which easily decomposes into calcium oxide and hydrazine. F. Schrader studied the action of **magnesium oxide.** When hydrazine hydrate is dropped on **mercuric oxide,** an explosion may occur. A. W. Browne and F. F. Shetterly said that an acid or alkaline soln. of hydrazine sulphate heated with red mercuric oxide gives neither ammonia nor hydrazoic acid, but when the yellow oxide is used with a slightly alkaline solu. at 0°, appreciable quantities of both ammonia and hydrazoic acid are formed. C. F. Hale and V. E. Nunez gave for alcoholic soln. of hydrazine, $N_2H_4.H_2O+2HgO =N_2+2Hg+3H_2O$. A soln. of **mercuric chloride** oxidizes hydrazine, forming neither ammonia nor hydrazoic acid. Solutions of mercuric salts, in the presence of mineral acids, are not reduced by hydroxylamine or hydrazine salts, but in a soln. of acetic acid in the presence of sodium acetate, heating with a hydrazine salt leads to the gradual precipitation of all the mercury: $2HgCl_2+N_2H_4 \rightarrow 4HCl +N_2+2Hg$. Ammoniacal soln. of mercuric salts are reduced immediately. E. Rimini gave for alkaline soln.: $N_2H_4.NaHSO_4+2HgCl_2+5NaOH=4NaCl +Na_2SO_4+2Hg+N_2+5H_2O$. The addition of a soln. of hydrazine chloride in a mixture of alcohol and ether to a similar soln. of mercuric chloride gives a white flocculent precipitate of $N_2H_4.HgCl_2$, which by contact with water forms $N_2H_2.Hg_2Cl_2$. An aq. soln. of hydrazine nitrate with mercuric nitrate furnishes $N_2H_4.Hg(NO_3)_2$, and with mercurous nitrate, $N_2H_4.Hg_2(NO_3)_2$. All these mercury compounds are explosive. O. Diels and S. Uthemann studied the action of mercuric oxide on various hydrazines; and N. R. Dhar, the induced reaction involving the effect of hydrazine on the reduction of mercuric chloride by oxalic acid. A. Benrath and K. Ruland observed that ceric sulphate in the presence of sulphuric acid oxidizes hydrazine in accord with the equation: $2N_2H_4+2Ce(SO_4)_2=N_2+(NH_4)_2SO_4+Ce_2(SO_4)_3$. A. W. Browne and F. F. Shetterly found **ammonium metavanadate** oxidizes hydrazine partly to hydrazoic acid, and partly so that the remaining nitrogen is evolved as nitrogen. K. A. Hofmann and F. Küspert used **vanadic sulphate** for a volumetric analytical process, the vanadyl sulphate produced being determined by titration of the soln. with potassium permanganate. T. Curtius and co-workers noted that hydrazine hydrate reduces **manganates** or **permanganates** to manganese dioxyhydrate; and I. M. Kolthoff said that in alkaline soln. or in a boiling hydrochloric acid soln., an excess of permanganate reduces hydrazine to nitrogen and ammonia. J. Petersen represented the reaction in the presence of 6–12 per cent. sulphuric acid by $17N_2H_4+13O=13H_2O+14NH_3+10N_2$; U. Roberto and F. Roncali, by $2KMnO_4+3H_2SO_4=K_2SO_4+2MnSO_4+5O+3H_2O$, and $5(N_2H_4.H_2SO_4)+5O_2=10H_2O+5H_2SO_4+5N_2$; but L. Medri prefers J. Petersen's equation. A. Purgotti represented the reaction with **manganese dioxide** in acid soln. by $2MnO_2+H_2SO_4+N_2H_4.H_2SO_4=2MnSO_4+4H_2O+N_2$; in neutral soln., a similar reaction occurs but hydrazine hydrate is formed. A. W. Browne and F. F. Shetterly observed that little ammonia and hydrazoic acid are formed in the oxidation of hydrazine by magnesium dioxide. A. W. Browne and F. F. Shetterly, and J. Petersen noted that a small proportion of hydrazoic acid is produced under certain conditions. The reaction was studied by F. Schrader. E. J. Cuy and M. E. Rosenberg believed that the presence of manganous salt formed during the reaction between hydrazine and potassium permanganate in acidic soln. is responsible for the fact that the amount of oxidizing agent needed for 1 mol. of hydrazine is variable, and is always much lower than the four eq. required for oxidation to nitrogen. The mechanism of the reaction depends on the intermediate formation of manganic salt, and the ionic equation $N_2H^{\cdot}_5+Mn^{\cdot\cdot\cdot}=NH^{\cdot}_4+\frac{1}{2}N_2+H^{\cdot}+Mn^{\cdot\cdot}$. According to F. Raschig, when hydrogen in hot sulphuric acid soln. is oxidized by **potassium permanganate,** ammonium sulphate is formed. A. W. Browne and F. F. Shetterly obtained a little hydrazoic acid by the action of **chromic sulphate,** and of **potassium chromate** on hydrazine. T. Curtius and co-workers, and F. Schrader found that solid **chromic anhydride** explodes in contact with a drop of hydrazine hydrate, and that **chromates** are reduced by aq. soln. of hydrazine, forming chromic hydroxide. A. Purgotti represented the reaction: $2K_2Cr_2O_7+5H_2SO_4+3(N_2H_4.H_2SO_4)=2Cr_2(SO_4)_3+2K_2SO_4+14H_2O+3N_2$ in soln. of sulphuric acid. L. Medri, and W. R. Hodgkinson also studied this reaction. E. J. Cuy and W. C. Bray found that the oxidation of hydrazine to nitrogen is only quantitative with an excess of potassium dichromate and a moderate amount of acid. T. Curtius and F. Schrader found that the **molybdates** are reduced by a soln. of hydrazine hydrate. A. W. Browne and F. F. Shetterly showed that in acid soln. **molybdenum trioxide** yields appreciable quantities of both hydrazoic acid and ammonia. The action of hydrazine salts on **tungstates** was studied by F. Schrader; and the action on tungstates, molybdates, and **tantalates** was studied by W. R. Hodgkinson.

According to T. Curtius, **ferric chloride** is reduced by hydrazine to ferrous chloride; a reaction investigated by E. Müller and G. Wegelin, and F. Schrader. E. J. Cuy found that in the reaction between hydrazine and a ferric salt in acid soln., one mol of hydrazine requires between one and two eq. of ferric salt for oxidation. The limiting reaction may be expressed as follows: $N_2H^{\cdot}_5+Fe^{\cdot\cdot\cdot}=NH^{\cdot}_4+\frac{1}{2}N_2+H^{\cdot}+Fe^{\cdot\cdot}$. A. W. Browne and F. F. Shetterly showed that **ferric oxide** and hydrazine in aq. soln. yield ammonia, but no hydrazoic acid, while **nickel sesquioxide** and **cobalt sesquioxide** yield ammonia and traces of hydrazoic acid. H. Franzen and O. von Mayer made complex cobalt salts—*e.g.* $CoCl_2(N_2H_4)_2$, etc.—with hydrazine in place of ammonia. T. Curtius found that platinum is precipitated when a soln. of hydrazine is added to a neutral soln. of **platinum**

chloride. W. R. Hodgkinson studied the action of hydrazine on **osmates.** L. A. Tschugaeff and M. Grigorieff found that hydrazine hydrate readily reacts with **platinum diamminodichloride,** forming a series of hydrazine derivatives.

The constitution of hydrazine.—As indicated above, the analyses and vapour density of hydrazine hydrate agree with $N_2H_4.H_2O$; the lowering of the f.p. of water agrees with the presence of $N_2H_4.2H_2O$ in aq. soln.; and, as J. W. Brühl, and R. Bach have shown, the mol. refraction of hydrazine is in agreement with the assumption that the nitrogen atoms are tervalent. Hydrazine itself is therefore supposed to be constituted $H_2{=}H{-}N{=}H_2$, and the monohydrate, as $H_2{=}N{-}NH_3{-}OH$, with one ter- and one quinquivalent nitrogen atom, or with two quinquivalent nitrogen atoms.

$$O<\begin{matrix}N\equiv H_3\\ \dot{N}\equiv H_3\end{matrix}$$

The chief uses of hydrazine depend on its strong reducing powers; on its introducing no fixed constitution into the soln.; and on its faculty of condensing with many compounds—*e.g.* the aldehydes—to form sparingly soluble compounds which easily crystallize. E. E. Jelley recommended their use as photographic sensitizing agents. The use of hydrazine in analytical work has been discussed by E. Knoevenagel and E. Ebler, P. Jannasch and co-workers, M. Schlötter, U. Roberto and F. Roncali, A. Purgotti, J. de Girard and A. de Saporta, by J. Schmidt in his *Die Anwendung der Hydrazine in der analytischen Chemie* (Stuttgart, 1907); by E. Elber in his *Ueber die Anwendbarkeit der Hydroxylamin- und Hydrazinsalze in der qualitativen Analyse,* Heidelberg, 1902; and his *Analytische Operation mit Hydroxylamin- und Hydrazinsalze* (Heidelberg, 1905); and by K. Biedermann, *Ueber quantitative Metalltrennungen mit Hydrazin* (Heidelberg, 1900).

Some analytical reactions of hydrazine.—When an aq. soln. of hydrazine is shaken with benzaldehyde, $C_6H_5.CO.H$, in acid or alkaline soln., a flocculent, sparingly-soluble precipitate of *benzalazine,* $C_6H_5.CH:N.N:CH.C_6H_5$, is formed. Copper sulphate soln. gives a sparingly soluble blue precipitate of $CuSO_4.N_2H_4.H_2SO_4$. According to L. M. Dennis and A. W. Browne, hydrazine is best detected by oxidizing it to hydrazoic acid, and identifying the latter by the ferric chloride test of T. Curtius and co-workers where a soln. of iron-alum or ferric chloride gives a sharp red coloration with sodium azide—unlike the red formed with thiocyanates, this colour is discharged with hydrochloric acid. The oxidation is effected by treatment with ethyl nitrite in the presence of an alkali. To detect hydroxylamine, hydrazine and ammonia in the presence of one another, T. Curtius and F. Schrader treated the acidified soln. with gold chloride, when, if but $\frac{1}{40000}$th of hydrazine be present, gold will be reduced; if the filtrate from the gold is made alkaline, a further reduction of the gold indicated the presence of hydroxylamine. If ammonia be also present, V. Meyer recommended treating the original soln. with benzaldehyde, removing the benzalazine by an ether extraction, and separating the hydroxylamine and ammonia by treatment with platinum chloride. To determine the amount of hydrazine in an acid soln., J. Petersen titrated it with permanganate; E. Rimini titrated the iodine liberated from potassium iodate—*vide supra*—with thiosulphate; and R. Stollé titrated hydrazine salts in the presence of an excess of sodium bicarbonate, with a standard of iodine—ammonium salts were supposed to be absent. E. Petersen measures the volume of nitrogen given off when the hydrazine soln. is treated with an ammoniacal soln. of a copper salt; K. A. Hofmann and F. Küspert used a sulphuric acid soln. of vanadic acid in the same way: $N_2H_4+O_2 \rightarrow N_2+2H_2O$; and E. Rimini warmed an alkaline soln. of hydrazine and mercuric chloride: $N_2H_4.H_2SO_4+6KOH+2HgCl_2 \rightarrow K_2SO_4+4KCl+6H_2O+2Hg+N_2$, and likewise measured the gas evolved.

§ 27. The Salts of Hydrazine, or Hydrazonium Salts

Hydrazine is strongly basic, and it forms two series of salts so that it can be regarded as a diacidic base. In general, however, with salts prepared in the ordinary way hydrazine behaves like a monoacidic base. In salts of the monoacidic series the hydrazinium radicle, so to speak, is the monad group, N_2H_5' ; and in the other series, the dyad group N_2H_6''. These groups are supposed to be respectively constituted :

$$\begin{array}{lcl} H_2{=}N & \qquad\qquad & H_3{\equiv}N- \\ H_3{\equiv}\dot{N}- & & H_3{\equiv}\dot{N}- \end{array}$$

G. Bredig,[1] and R. Bach concluded that while the first acidic function is nearly the same as that of ammonium hydroxide, the second acidic function of the base is so weak in aq. soln. that the corresponding salts are almost completely hydrolyzed. T. Curtius and H. Schulz said that a dihydrate exists in aq. soln. because the cryoscopic data gave a mol. wt. of 68. These data, however, can be interpreted on the basis either of a monohydrate or of a dihydrate. All this does not decide whether hydrazine is a monoacidic or a diacidic base. E. C. Gilbert also found that in the electrometric titration of a 0·1*M*-soln. of hydrazine hydrate with acids, there is only one point of inflection, Fig. 51. The *x* indicates where the second inflection would occur. Each division on the ordinate represents 100 millivolts.

T. Curtius and H. Schulz prepared **hydrazine difluoride,** $N_2H_6F_2$, by adding hydrofluoric acid to an alcoholic soln. of hydrazine hydrate; and also by evaporating an aq. soln. of the base neutralized with hydrofluoric acid. *Hydrazine monofluoride,* N_2H_5F, has not been prepared. The difluoride furnishes cubic crystals which melt at 105°, and sublime undecomposed. The salt is readily soluble in water; sparingly soluble in alcohol; and insoluble in ether, and benzene.

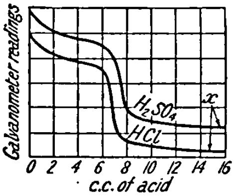

FIG. 51.—Electrometric Titration of Solutions of Hydrazine with Acids.

T. Curtius and H. Schulz prepared **hydrazine monochloride,** N_2H_5Cl, by heating the dichloride to 140°–160°; R. von Rothenburg obtained it by the action of hydrazine hydrate on benzoyl chloride; and F. Raschig, by the action of ammonia on monochloroamine, and by the action of hypochlorites on aq. ammonia. The long, needle-like crystals melt at 89°. The heat of neutralization, heat of soln., and heat of formation were measured by M. Berthelot and C. Matignon, and R. Bach as indicated in connection with hydrazine; R. Bach also measured the mol. refraction—*vide* hydrazine. T. Curtius and co-workers found that the salt is readily soluble in water, sparingly soluble in boiling alcohol, and the soln. on cooling furnishes well-developed crystals. According to F. Friedrichs, the monochloride is readily soluble in liquid ammonia and the soln. separates into two layers. Double salts with zinc, cadmium, mercury, tin, copper, and platinum were described by T. Curtius and F. Schrader, and F. Ranfaldi.

By treating an alcoholic soln. of hydrazine hydrate with chlorine, T. Curtius and H. Schulz prepared **hydrazine dichloride,** $N_2H_6Cl_2$, part of the hydrazine is at the same time decomposed: $3(N_2H_4.H_2O)+2Cl_2=3H_2O+N_2+2N_2H_6Cl_2$. T. Curtius obtained it by double decomposition of the sulphate with barium chloride; R. von Rothenburg, by the action of hydrazine hydrate on benzoyl chloride; and T. Curtius and R. Jay, and E. Ebler by boiling benzalazine with hydrochloric acid: $N_2(C_6H_5.CH)_2+2H_2O+2HCl=N_2H_6Cl_2+2C_6H_5.COH$. T. Curtius said that the salt crystallizes from water in octahedra belonging to the cubic system. R. W. G. Wyckoff said that the crystal unit is a cell 7·89 A. in length containing four mols. The structure is said to be like that of the nitrates of the alkaline earths, with hydrazine radicles in place of the metal chlorine atoms in place of the nitrate radicles. The distance between adjacent chlorine atoms is 3·96 A., and between the chlorine and nitrogen atoms, about 3·14 A. H. Schiff and U. Monsacchi found the sp. gr. is 1·4226 at 20°/4°, and they represented the sp. gr., *D*, of aq. soln. containing *w* per cent. of the salt to be $D=0·99826+0·00436w+0·00017w^2$, at 20°. There is therefore a contraction during the dissolution of the salt, and the increase in the contraction is almost proportional to the quantity of salt dissolved. T. Curtius gave 198° for the m.p. of the salt which decomposes at the lower temp.—say, 180°—giving off hydrogen chloride, and forming hydrazine monochloride as a clear glass. If heated rapidly on a hot plate, it decomposes with a hissing noise or maybe with a detonation. If heated for a long time at 140°, it decomposes: $2N_2H_6Cl_2=2NH_4Cl+2HCl+N_2+H_2$. The heats of neutralization, and soln. by M. Berthelot and C. Matignon, and R. Bach, and the mol. refraction by R. Bach were discussed in connection with hydrazine—*vide supra.* E. C. Gilbert found that in the electrometric titration of $0·025M$-soln. of hydrazine sulphate or dihydrochloride with $0·1112N$-NaOH, Fig. 52, there are two inflections corresponding respectively

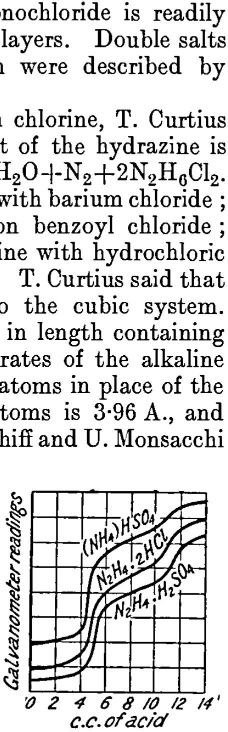

FIG. 52.—Electrometric Titration of Hydrazine Salts with Sodium Hydroxide.

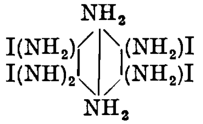
with the first and second eq. of base. This confirms the conclusion of G. Bredig, and R. Bach that the hydrazine salts containing two eq. of acid are largely hydrolyzed in dil. soln., or dissociated into the mono-salt and free acid. The first inflection corresponds with the neutralization of the hydrogen ion thus produced and the second to the formation of the non-ionized base, N_2H_5OH, or $N_2H_6(OH)_2$. The first inflection is sufficiently sharp to indicate that the use of hydrazine in alkalimetry as recommended by R. Stollé is practicable. The result with ammonium hydrosulphate is added for comparison. Each division on the ordinate represents 100 millivolts. According to T. Curtius and co-workers, the dichloride is hygroscopic, readily soluble in water, and sparingly soluble in aq. alcohol. V. H. Veley measured the rate of hydrolysis of hydrazine dichloride. The dry salt was found by E. Ebler to be completely decomposed by dry chlorine at about 100° ; $N_2H_6Cl_2+2Cl_2=6HCl+N_2$—no nitrous oxide was formed; when warmed with bromine water, much gas is evolved, and no solid residue is obtained on evaporation. E. Ebler studied the action of soln. of the dichloride on various salts—stannic, arsenic, molybdic, tungstic, vanadic, platinum, gold, silver, copper, and bismuth. T. Curtius and co-workers, and J. Thiele discussed the action on platinic chloride in alcoholic soln., a yellow precipitate, $(N_2H_5)_2PtCl_6$, is formed, but in aq. soln., the platinic salt is reduced to platinous chloride. K. Seubert and J. Carstens found the velocity of the reduction of chromic anhydride by hydrazine is very fast, and is proportional to the conc. of the chromic anhydride, the hydrazine and the hydrochloric acid present in the soln. The dihalide salts are readily soluble in water, and almost insoluble in alcohol; the monohalide salts are readily soluble in water and warm alcohol; and both are almost insoluble in ether and benzene. The dihalide salts crystallize in the cubic system. According to P. Borissoff, the hydrazine salts are usually isomorphous with the corresponding ammonium salts.

T. Curtius and H. Schulz found that if hydrazine hydrate be allowed to stand over bromine, the base is decomposed, forming nitrogen and hydrogen bromide; but they made **hydrazine monobromide,** N_2H_5Br, as a white crystalline mass, by the action of bromine on hydrazine hydrate suspended in chloroform, or by treating an alcoholic soln. of hydrazine hydrate with hydrobromic acid, and precipitating the salt with ether. The salt can be recrystallized from soln. in warm alcohol. The crystals are anisotropic, and melt at 80°. They also made **hydrazine dibromide,** $N_2H_6Br_2$, by evaporating a soln. of hydrazine hydrate mixed with an excess of hydrobromic acid; by decomposing benzalazine with hydrobromic acid; and by evaporating a mixed soln. of the monobromide and hydrobromic acid. The white powder melts at 195°. The mol. wt. in aq. soln. is only one-fourth the normal value.

T. Curtius and H. Schulz prepared **hydrazine monoiodide,** N_2H_5I, by adding tincture of iodine to a dil. alcoholic soln. of hydrazine hydrate until a point is reached when a drop of the iodine soln. produces a yellow coloration: $5(N_2H_4.H_2O)+2I_2=4N_2H_5I+5H_2O+N_2$. The salt is obtained by evaporation. They also obtained it by evaporating an aq. soln. of hydrazine hydrate and an excess of hydriodic acid; by adding ether to a mixed soln. of hydrazine hydrate and hydriodic acid; and by evaporating a soln. of hydrazine ditritaiodide with an excess of hydriodic acid. The long, colourless, prismatic crystals melt at 127°, and then explode. The mol. wt. of the salt in aq. soln. is half the normal. If the monoiodide be evaporated with an excess of conc. hydriodic acid no **hydrazine diiodide,** $N_2H_6I_2$, is formed; but this salt is produced when benzalazine is treated with fuming hydriodic acid; and, according to R. von Rothenburg, when hydrazine hydrate is treated with methyl iodide. According to T. Curtius and H. Schulz, the product is very hygroscopic, and is coloured brown on exposure to light. It melts at 220°. Its mol. wt. in aq. soln. is one-fourth the normal. R. von Rothenburg found that the diiodide furnishes benzalazine when treated with benzaldehyde; and if hydrazine hydrate be treated with ethyl or isoamyl iodide, **hydrazine ditritaiodide,** $(N_2H_4)_3(HI)_2$, is formed. This salt was previously obtained by T. Curtius and

H. Schulz by adding iodine to a conc. alcoholic soln. of hydrazine hydrate up to the



point at which white crystals are formed. The constitution of the salt is represented by the above graphic formula. The needle-like crystals are optically biaxial; they melt at 90°. The salt is very hygroscopic; and is very soluble in water. The mol. wt. of the salt in aq. soln. is one-fifth the normal—hence the salt dissociates in aq. soln. into three mols of hydrazine hydrate, and two mols of hydrogen iodide. When the aq. soln. is evaporated with hydriodic acid, the monoiodide is formed.

The only evidence of the existence of **hydrazine sulphide** has been discussed in connection with the dissolution of sulphur in hydrazine. The preparation of **hydrazine disulphate,** $N_2H_6SO_4$—generally called *hydrazine sulphate*—has been discussed in connection with the production of hydrazine itself. Its preparation was described by B. P. Orelkin and co-workers. It is produced when a soln. of hydrazine hydrate is crystallized from an excess of sulphuric acid It can be regarded as **hydrazine hydrosulphate,** $N_2H_5.HSO_4$; F. Sommer and K. Weise called it *monohydrazonium sulphate.* It was obtained by T. Curtius, and T. Curtius and R. Jay, in tabular or prismatic crystals which are biaxial. The crystals belong to the rhombic system, and T. Liweh gave for the axial ratios, $a:b:c$ $=0.74532:1:0.82825$; and A. Fock, $0.90117:1:0.60404$. The cleavage is complete. A. P. Sabanéeff found the salt to be isomorphous with hydroxylamine amidosulphate, $NH_2SO_3H.NH_2OH$, and ammonium hydroxylaminomonosulphonate, $NH_4SO_3.NH(OH)$. The sp. gr. is 1·378. T. Curtius and co-workers say that the salt suffers no change at 250°, and that it melts at 254° with the evolution of gas. When melted in a test-tube over the flame, it decomposes explosively into ammonium sulphite, sulphur dioxide, hydrogen sulphide, and much sulphur. The thermal data by R. Bach, and M. Berthelot and C. Matignon are indicated in connection with hydrazine. Fig. 52 shows the result of the electrometric titration of the sulphate with sodium hydroxide. T. Curtius found that the salt is sparingly soluble in cold water, but readily soluble in hot water; T. Curtius and R. Jay said that 100 grms. of water, at 22°, dissolve 3·055 grms. of the salt. The solubility of the disulphate was measured by F. Sommer and K. Weise. Expressing conc., S, in grams of salt per 100 grms. of soln., it was found that in water, Fig. 53,

	20°	25°	30°	40°	50°	60°	70°	80°
S .	2·794	3·302	3·746	4·987	6·538	8·322	10·495	12·580

in sulphuric acid at 25°,

H_2SO_4 .	0	0·4897	4·887	26·59	49·00	116·18	144·18 grms. per litre
S . .	3·302	3·143	2·680	1·541	1·026	0·518	0·4318

in hydrochloric acid at 25°,

HCl .	0	0·3645	3·645	18·25	36·45	66·08 grms. per litre
S . .	3·302	3·156	2·876	2·652	2·639	2·615

and in acetic acid at 25°,

$CH_3.COOH$	0	0·5157	6·8963	33·306	63·00	117·38 grms. per litre
S . .	3·302	3·198	3·147	2·903	2·737	2·323

According to T. Curtius, the disulphate is not dissolved by alcohol. R. Bach reported that the salt in aq. soln. is resolved into the ions $N_2H_5{}^{\cdot}$ and $HSO_4{}'$; T. Curtius and H. Schulz found that the mol. wt. of the salt in aq. soln. is half that of the normal salt; and F. Sommer and K. Weise say that the f.p. measurements correspond with ionization into three ions. According to F. Friedrichs, the salt undergoes a reversible reaction with liquid ammonia, $N_2H_6SO_4 + 2NH_3 \rightleftharpoons (NH_4)_2SO_4 + N_2H_4$—*vide* hydrazine. The disulphate does not react with nor dissolve in liquid sulphur dioxide. Most of the reactions indicated in connection with hydrazine (*q.v.*) were made with hydrazine sulphate. According to F. Sommer and K. Weise, hydrazine disulphate does not yield double salts with other metallic sulphates under ordinary conditions, being largely hydrolyzed into the monosulphate and sulphuric acid. It dissolves in conc. sulphuric acid and deposits colourless crystals of **hydrazine hydrodisulphate,** $N_2H_6SO_4,H_2SO_4$. A definite double salt is obtained by adding the solid sulphate to a hot, concentrated soln. of ammonium sulphate in large excess. Colourless crystals, stable in air but decomposed by water, are obtained having the composition of **ammonium hydrazine disulphate,** $N_2H_6SO_4,(NH_4)_2SO_4$. This is the only known double salt of hydrazine disulphate. P. F. Frankland and R. C. Farmer found that hydrazine sulphate is not attacked or dissolved by liquid nitrogen peroxide.

If a soln. of hydrazine sulphate be exactly neutralized with sulphuric acid, and evaporated, finally in vacuo, crystals of the normal sulphate, **hydrazine monosulphate,** $2N_2H_4.H_2SO_4$, or $(N_2H_5)_2SO_4$, are produced. F. Sommer and K. Weise call it *dihydrazonium sulphate,* and they prepared it by stirring a hot soln. of the ordinary sulphate with an excess of barium carbonate, the reaction being $2N_2H_6SO_4 + BaCO_3 = (N_2H_5)_2SO_4 + BaSO_4 + H_2O + CO_2$. The soln. becomes alkaline, and is then made faintly acid with sulphuric acid and filtered. The filtrate is evaporated and cooled in ice, when a crystalline powder of the **monohydrate** $(N_2H_5)_2SO_4,H_2O$ separates, and may be recrystallized from water, when it forms large, transparent, doubly-refracting, tabular crystals. It is much more soluble in water than ammonium sulphate. The solubility curve, Fig. 53, consists of two branches, intersecting at the transition point between the monohydrate and anhydrous salt, the transition temp. of which is 47·3°. The solubility data expressed in grams of the salt, *S*, per 100 grms. of soln., are as follow :

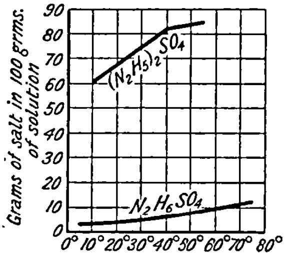


FIG. 53.—The Solubilities of the two Hydrazine Sulphates.

	25°	35°	45°	50°	55°	60°
S	66·91	71·28	78·54	82·33	83·40	84·72

According to C. Montemartini and L. Losana, a 10 per cent. aq. soln. of hydrazine sulphate shows an arrest at 35° and one at 55° on the density-temp. curve. The anhydrous salt forms long, colourless prisms. T. Curtius reported that this salt is deliquescent in air; and is almost insoluble in alcohol. The thermal data by R. Bach have been discussed in connection with hydrazine, $(2N_2,5H_2,S,2O_2,Aq.) = 230·3$ Cals. T. Curtius gave 85° for the m.p.; F. Sommer and K. Weise, 118·9°. L. Longchambon proved that the salt is optically active and gives enantiomorphic crystals; for $\lambda = 436$, 516, and 579, the optical rotations are respectively 4°, 3·05°, and 2·8°. T. Curtius and F. Schrader described double salts of the type $MSO_4.(N_2H_4)_2H_2SO_4$, where M denotes Cu, Fe, Co, Ni, Cd, Zn, and Mn; and F. Sommer and K. Weise assume them to be constituted $M(SO_4.NH_3.NH_2)_2$. They did not succeed in making the double salts with sodium, potassium, or ammonium, but they made the double salt with lithium sulphate, $Li_2SO_4.(N_2H_5)_2SO_4$; calcium sulphate, $CaSO_4(N_2H_5)SO_4$; magnesium sulphate, $MgSO_4.(N_2H_5)_2SO_4.4H_2O$; aluminium sulphate, or *hydrazine-alum,* $(N_2H_5)Al(SO_4)_2.12H_2O$; and chromium sulphate, $(N_2H_5)Cr(SO_4)_2.12H_2O$. When hydrazine sulphate is added to a soln. of nickel sulphate, a reddish-violet precipitate of the trihydrazinate is first obtained, but dissolves to a blue soln., from which blue crystals of a salt, **nickel hydrazinotriaquosulphate,**

$NiSO_4,N_2H_4,3H_2O$, separate after a day. This salt is insoluble and is stable in air, but is decomposed by heating with water.

According to T. Curtius and R. Jay, aq. soln. of hydrazine hydrate attract carbon dioxide from atm. air, and when the soln., sat. with that gas, is evaporated in vacuo, a caustic, syrupy liquid remains—presumably **hydrazine carbonate.** The product is very hygroscopic, sparingly soluble in alcohol, and, according to A. Purgotti and L. Zanichelli, is decomposed by heat.

According to A. P. Sabanéeff and E. Dengin, normal **hydrazine mononitrate,** $N_2H_5NO_3$, was prepared by neutralizing hydrazine hydrate with nitric acid, using litmus as indicator, and crystallizing the liquid. F. Sommer made it by mixing hydrazine disulphate and barium nitrate, adding sodium carbonate to remove free acid, and separating the sodium and hydrazine nitrates by crystallization, fusion at 70°, and recrystallization from methyl alcohol. It is necessary to fuse for some time in vacuo to remove the last traces of alcohol. The salt melts at about 69°; F. Sommer gave 70·71°, and W. R. E. Hodgkinson gave 70°. The last-named said that the salt can be kept for a long time at 100° without change, and that at 200°, in vacuo, it decomposed: $4N_2H_5NO_3=5N_2+2NO+10H_2O$. A. P. Sabanéeff and E. Dengin said that the salt begins to volatilize without decomposition at 140°, and added that it may be heated to nearly 300° without decomposition. It detonates when heated quickly over the free flame. W. R. E. Hodgkinson found that when heated under press., the salt decomposes with explosive violence, but under ordinary press., it burns rapidly. According to F. Sommer, by analogy with ammonium nitrate, hydrazine nitrate, $N_2H_5NO_3$, might be expected to exhibit enantiomorphic inversions, but if such do occur, they have not been detected by thermal, dilatometric, or solubility methods. By cooling from 100°, a labile modification appears at 62°, differing from the stable crystals, but this always changes to the stable form before 40° is reached. The labile crystals melt at 61·8°. A. P. Sabanéeff and E. Dengin found the mononitrate to be very soluble in water; and F. Sommer gave for the solubility, *S*, in grams per 100 grms. of sat. soln.:

	10°	15°	20°	25°	30°	40°	50°	60°
S .	63·63	68·47	72·70	76·61	80·09	85·86	91·18	96·51

The solubility curve is continuous from 10° up to the m.p. A. P. Sabanéeff and E. Dengin said that the mononitrate is very sparingly soluble in absolute alcohol; the hot alcoholic soln. furnishes needle-like crystals on cooling. With conc. sulphuric acid, nitrous oxide is turbulently evolved; dil. sulphuric acid (1 : 1) decomposes the salt, forming hydrazoic acid; and with phosphorus pentachloride, hydrazine monochloride is formed. According to W. R. E. Hodgkinson, the aq. soln. has very little action on metals such as zinc, cadmium, and magnesium, which are strongly acted on by soln. of ammonium nitrate, but the fused salt acts more vigorously than fused ammonium nitrate. Zinc, copper, and most other metals, as well as oxides, sulphides, nitrides, and carbides, cause a flaming decomposition at temp. little above the m.p. Cobalt and nickel that have been thoroughly melted behave like the other metals towards fused hydrazine nitrate, but commercial cubes of cobalt cause a very violent action, followed almost immediately by a severe explosion. Nitrates of bases, such as aniline and toluidine, both in soln. and when fused, behave towards most of the metals in a way analogous to ammonium nitrate.

A. P. Sabanéeff and E. Dengin made **hydrazine dinitrate,** $N_2H_6(NO_3)_2$, by double decomposition with hydrazine disulphate and barium nitrate, or by half neutralizing nitric acid with hydrazine hydrate. On evaporating the soln., needles or plates are formed. The aq. soln. cannot be conc. on the water-bath to more than 30 per cent. nitrate because decomposition then occurs. Alcohol precipitates the mononitrate from the aq. soln. The m.p. is 103°–104° with rapid heating; when slowly heated, it decomposes at 80°–85° without melting, forming hydrazoic acid, nitric acid, nitrogen, water, hydrazine mononitrate, and ammonium nitrate. The salt also decomposes when kept over sulphuric acid at ordinary temp., forming hydrazoic acid, etc.

A. P. Sabanéeff prepared normal or primary **hydrazine phosphate,** or **hydrazine dihydrophosphate,** $N_2H_5.H_2PO_4$, by double decomposition with hydrazine disulphate and barium hydrophosphate; and by neutralization of hydrazine hydrate with phosphoric acid using methyl orange as indicator. The salt is readily soluble in water; it melts without decomposition at about 82°; and its f.p. in water is about half that required to give the normal mol. wt., so that the salt furnishes two ions per mol. It is isomeric with hydroxylamine amidophosphate, $OP(OH)(O.NH_4O)NH_2$. He also made **hydrazine bisdihydrophosphate,** $N_2H_6(H_2PO_4)_2$, by double decomposition with hydrazine disulphate and barium dihydrosulphate; and by dividing a soln. of phosphoric acid in two equal parts, neutralizing one part with hydrazine hydrate, using methyl orange as indicator, and mixing the two soln. Crystals are readily obtained on evaporation. This salt is less soluble than the normal salt. Its f.p. in water indicates the formation of three ions. The salt is isomeric with hydroxylamine amidohypophosphate, $(NH_3OH).H_2P_2O_6$.

§ 28. Hydrogen Azide, Hydrazoic Acid, or Azoimide

Nitrogen gas is rivalled only by argon and its congeners in its reluctance to take part in chemical changes; but when united with other elements it furnishes a profusion of derivatives remarkable for their great chemical activity. Hence, M. O. Forster[1] could say that nitrogen is one of the most versatile forms of elemental matter. As previously indicated, the extraordinary inertness of ordinary nitrogen, N_2, is attributed to the tenacity with which the two atoms of the mol. remain in combination. In ammonia, and the amines or amides, one nitrogen atom is united with other elements; in hydrazine, the diamides, or diazo-compounds, two nitrogen atoms are grouped together; and in azoimide or hydrazoic acid, or the triazo-compounds, a complex of three nitrogen atoms acts as a monad radicle. The different compounds of hydrogen and nitrogen which have been prepared are as follow:

Bases.		Acid.	Salts.		
NH_3	N_2H_4	N_3H	N_4H_4	N_5H_5	N_7H_9
Ammonia.	Diamide or Hydrazine.	Azoimide or Hydrazoic acid.	Ammonium azide.	Hydrazine azide.	Nitrogen trihydrozinide.

E. J. Maumené[2] claimed to have made a salt of **imide,** or rather **diimide,** NH, or N_2H_2, *i.e.* H—N=N—H, namely, *diimide hydrochloride,* $N_2H_2.2HCl$, by the dry distillation of ammonium chloroplatinate, $(NH_4)_2PtCl_6=4HCl+Pt+N_2H_2.2HCl$, when the salt in question collected in six-sided rhombic crystals, in the neck of the retort. This claim has not been established; T. Curtius and R. Jay did not succeed in making it by heating hydrazine hydrochloride.

While the doubling of ammonia on itself produces diamide or hydrazine, N_2H_4, *i.e.* $H_2=N—N=H_2$, the attempt to extend the operation one stage further, so as to produce N_3H_5, *i.e.* $H_2=N—NH—N=H_2$, **triamide,** or **triazane,** has not been successful.

$$N—H<\begin{matrix}H\\H\end{matrix}$$

Ammonia, NH_3.

$$H—N<\begin{matrix}NH_2\\H\end{matrix}$$

Diamide, $NH_2.NH_2$.

$$N—H<\begin{matrix}NH_2\\NH_2\end{matrix}$$

Triamide, $NH_2.NH.NH_2$.

F. Raschig thought that in the reaction between sodium hydroxide and chloramine (*q.v.*), it is probable that there is formed some **triimide,** N_3H_3, or

For sodium triimide, *vide* the action of sodium on hydrazine. The inclination of nitrogen to form long chains and closed rings is far less than is the case with carbon; with the latter, there seems an almost unlimited number of hydrogen compounds; with nitrogen, comparatively few are known, and these are usually unstable bodies, often explosive.

J. Thiele and W. Osborne,[3] and O. Dimroth, however, did succeed in preparing organic derivatives of the open chain triazane or triamide which they named **prozane,** $H_2N.NH.NH_2$, after the well-known hydrocarbon *propane,* $CH_3.CH_2.CH_3$; and H. von Pechmann has prepared organic derivatives of **buzane,** or **tetrazone,** $H_2N.NH.NH.NH_2$, named after the hydrocarbon *butane,* $CH_3.CH_2.CH_2.CH_3$. Still further, T. Curtius prepared organic derivatives of what he called **buzylene,** $NH_2.NH.N:NH$, after the hydrocarbon *butylene,* $CH_3.CH_2.CH:CH_2$; the four-link chains of the nitrogen-hydrogen compounds are sometimes called *tetrazenes* (also *tetrazones*), and both symmetrical $(NH_2.N:N.NH_2)$ and unsymmetrical $(NH_2.NH.N:NH)$ derivatives have been prepared—the former by A. P. N. Franchimont and H. van Erp, and the latter by A. Wohl and H. Schiff. Organic derivatives were also made by E. Fischer, A. Michaelis, A. Angeli, J. R. Bailey, R. Stollé, E. Renouf, etc., and were discussed in the monograph of H. Wieland. Organic derivatives of a chain of five nitrogen atoms $HN:N.NH.N:NH$, *pentazene,* analogous with the di-olefine hydrocarbon *pentadiene,* $CH_2:CH.CH_2.CH:CH_2$, have been made by H. von Pechmann and L. Frobenius. The longest known chain of nitrogen atoms is an eight-link chain in the organic derivatives of **octazone,** $NH:N.NH_2.N:N.NH_2.N:NH$, prepared by A. Wohl and H. Schiff.

When T. Curtius attempted to add another nitrogen atom to the two-linked chain in diamide so as to form a three-linked chain, he found that the two terminal nitrogen atoms linked with one another to form a closed ring of three nitrogen atoms:

the so-called **triazo-group,** which, in its simplest form, is represented by **hydrazoic acid,** or **azoimide,** N_3H. There is a large class of organic compounds, including many artificial colouring agents, in which the triazo-group is the dominant radicle. The simpler compounds of nitrogen—ammonia, and hydrazine—have basic properties, forming salts with acids, the triazo-hydride has acidic properties, hence the name hydrazoic acid, HN_3. Indeed, it forms with ammonia the curious salt N_4H_4, *i.e.* ammonium azide, $(NH_4)N_3$; and with hydrazine, the still more curious salt N_5H_5—*i.e.* hydrazine azide, $N_2H_4.HN_3$.

When nitrous acid acts on ammonia, say by heating ammonium chloride with sodium nitrite, both atoms of nitrogen are liberated in the form of diatomic mols. The fundamental equation is

$$\begin{array}{l}NH_2\\ \dot{H}\end{array}+NO.OH\rightarrow\begin{array}{c}N\\ \vdots\\ N\end{array}+2H_2O$$

but in 1890, T. Curtius found that if hydrazine be used in place of ammonia, the attack of nitrous acid furnishes the simplest known form of the triazo-group, N_3H. The fundamental equation is

$$\begin{array}{l}NH_2\\ \dot{N}H_2\end{array}+NO.OH\rightarrow\begin{array}{c}N\\ \vdots\\ N\end{array}>N-H+2H_2O$$

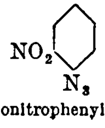
This synthesis of hydrazoic acid, said D. I. Mendeléeff, marks one of the most important achievements of the year 1890. This remarkable acid has no structural parallel among the inorganic acids, and in that respect it occupies an isolated position. The phenyl derivative of this acid, $C_6H_5.N_3$, was discovered by J. P. Griess in 1867.

General usage has not definitely fixed a name for this compound. T. Curtius called it *azoimide ;* H. C. Jones, *triazoic acid ;* L. M. Dennis and co-workers, *hydronitric acid ;* and D. I. Mendeléeff, *hydronitrous acid* The term "azoimide" does not indicate the acid character of the compound, nor the analogy between it and the halogen acids. The term "hydronitric" is presumably intended to indicate the absence of oxygen, and make the name conform with the other hydro-acids. To avoid confusion with the other oxy-nitrogen acids, and to give a hint of the relationship of the acid with the triazo-group, hydrazoic acid is commonly preferred. In any case, the name of the salts should be related with that of the parent acid. L. M. Dennis and co-workers, who used the term *hydronitric acid,* call the salts *trinitrides,* to distinguish them from the ordinary nitrides of the type K_3N, and to keep up the analogy with the halides. E. C. Franklin regarded it as ammoniated nitric acid, and called it *ammononitric acid ;* and A. W. Browne and F. Wilcoxon, in allusion to its formation by the hydrazinolysis of nitrous acid, *hydrazinonitrous acid* or *ammonohydrazonitric acid—vide infra.* If *hydrazoic acid* be applied to this compound, the salts, for the same reason, can be called *azides.* The root of the word "hydrazoic" is of course *azote,* the term used in France for nitrogen.

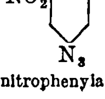
The fundamental reaction just indicated is not well adapted to the production of hydrazoic acid or its salts in quantity. Following L. M. Dennis and co-workers,[4] the methods which have been proposed for the preparation of hydrazoic acid, may be conveniently summarized :

(1) *The action of a compound containing a chain of two nitrogen atoms united to positive atoms or radicles* (e.g. *hydrazine,* $H_2N.NH_2$) *upon a compound containing a single nitrogen atom united to a negative radicle* (e.g. *nitrous acid,* HNO_2).—In the classical experiments of T. Curtius, in conjunction with G. Struve, benzoylazide, $C_6H_5.CO.N_3$, was made by the action of sodium nitrite and acetic acid on benzoylhydrazine, $C_6H_5.CO.NH.NH_2$; and the product was hydrolyzed by a soln. of sodium hydroxide. The resulting sodium azide was mixed with sulphuric acid and distilled to get the hydrazoic acid itself. Sodium ethylate or alcoholic ammonia was later used for the hydrolysis. Hippuryl hydrazine was also found to give better results than benzoyl hydrazine.

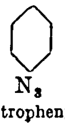
In connection with the hydrolysis of benzoylazide, it is interesting to recall that triazobenzene or phenylazide, $C_6H_5N_4$, is so stable that it cannot be directly hydrolyzed by the action of acids on alkalies to form hydrazoic acid, but E. Nölting and E. Grandmougin were able to show that if an acidic radicle, say a nitro-group, be introduced into the phenyl radicle—say by treatment with nitric acid whereby *p*-nitrophenylazide, $C_6H_4(NO_2)N_3$, is formed—the product is readily hydrolyzed by alkali-lye. Similar remarks apply to the ortho-derivatives, while, curiously enough, the meta-derivatives are not so readily hydrolyzed.



Orthonitrophenylazide.



Metanitrophenylazide.



Para-nitrophenylazide.

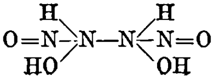
T. Curtius prepared hydrazoic acid by the action of the red gases evolved from a mixture of nitric acid and arsenic trioxide upon a dil. ice-cold soln. of hydrazine hydrate; and A. Sabanéeff and E. Dengin obtained a 10–12 per cent. yield of hydrazoic acid by heating hydrazine sulphate with nitric acid (sp. gr. 1·3). The formation of hydrazoic acid by heating various hydrazine salts (*q.v.*) was studied by J. W. Turrentine.

There are many different interpretations of the reaction between hydrazine and nitrous acid since these two substances can furnish a variety of products: for instance, according to A. Angeli: $N_2H_4+HNO_2=N_3H+2H_2O$; M. Dennstedt and W. Göhlich: $3N_2H_4+6HNO_2=2N_3H+2N_2O+O_2+N_2+8H_2O$; J. de Girard and A. de Saporta: $N_2H_4+2HNO_2=N_2+2NOH+2H_2O$; E. Francke: $N_2H_4+HNO_2=NH_3+2NO+H_2O$; H. K. Dey and B. B. Sen: $2N_2H_4+3HNO_2=N_2+2N_2O+NH_3+4H_2O$. F. Sommer and H. Pincas have shown that the reaction is not really so involved as these different equations might suggest if the nature of the soln.—acid or neutral—be taken into consideration. They show that hydrazine and nitrous acid react in neutral soln. to form stable hydrazine nitrite which is decomposed by heat into ammonia and nitrous oxide: (i) $N_2H_4+HNO_2=N_2H_5,NO_2$; and $N_2H_5.NO_2=NH_3+N_2O+H_2O$, a change which is accelerated by the presence of free nitrous acid or other weak acids. With strong acids, the reaction is different: (ii) $N_2H_4+HNO_2=HN_3+2H_2O$ (T. Curtius' reaction); or (iii) $N_3H+HNO_2=N_2+N_2O+H_2O$ (J. Thiele's reaction) in which the hydrazoic acid is destroyed. Hence, in neutral soln., the reactions can be referred to the decomposition of the mols. of hydrazine mononitrite: $N_2H_5NO_2=NH_3+N_2O+H_2O$; and of hydrazine dinitrite: $N_2H_6(NO_2)_2=N_2O+H_2O+NH_4NO_2$ (N_2+2H_2O). J. Thiele's reaction proceeds with a greater velocity than T. Curtius' reaction. Increasing the conc. of the acid favours J. Thiele's reaction and this lowers the yield of hydrazoic acid. The best yield was obtained by using 400 c.c. of a 16·5 per cent. soln. of phosphoric acid, 27·6 grms. of hydrazine chloride, and a soln. of 1·35 grms. of sodium nitrite in 400 c.c. of water. Assuming that this argument is correct, it follows that to obtain a high yield of hydrazoic acid, the conc. of the acid should be high, and the hydrazine conc. low to avoid reaction (i); but if the conc. of the acid be too high, an excess of hydrazine will be needed for protection against reaction (iii). F. Sommer and H. Pincas consider that nitrosohydrazine is an intermediate product of reactions (i) and (ii): $NH_2.NH_2+HO.N:O=NH_2.N:N.OH+H_2O$. The nitrosohydrazine exists in the nitroxyl form, $NH_2.N:N.OH$, and the true nitrosoform $NH(NH_2)NO$. In strong acid soln. the the latter form preponderates and readily breaks down into ammonia and nitrous oxide, whereas in weak acid soln. (*e.g.* acetic acid), an equilibrium may exist leading to both reactions (i) and (ii). The reaction was further discussed by F. Sommer, A. W. Browne and O. R. Overman, and A. Angeli. The last-named assumed that in the formation of hydrazoic acid from hydrazine, an intermediate compound, probably tetrazone, $NH_2.N:N.NH_2$, is formed.

S. M. Tanatar made hydrazoic acid by treating a 3·3 per cent. soln. of nitrogen chloride in benzene with an aq. soln. of hydrazine sulphate. The yield approximated 36 per cent. A. Angeli treated hydrazine sulphate with a cold sat. soln. of silver nitrite when a crystalline precipitate of silver azide was produced in a short time:

$$\begin{matrix}NH_2\\ \dot{N}H_2.H_2SO_4\end{matrix}+NO.OAg\rightarrow\begin{matrix}N\\ \vdots\\ N\end{matrix}\!>\!N-Ag+2H_2O+H_2SO_4$$

M. Dennstedt and W. Göhlich used potassium nitrite and hydrazine disulphate: $3(N_2H_4.H_2SO_4)+6KNO_2+3H_2SO_4=2N_3H+8H_2O+6KHSO_4+O_2+N_2+2N_2O$. The monosulphate, $(N_2H_4)_2.H_2SO_4$, gives a mixture of ammonia and hydrazine. It is supposed that an unstable hydrazine nitrite, $N_2H_4.2HNO_2$, is first formed with nitrogen quinquevalent:



Three mols. of this nitrite condense with the elimination of six mols. of water; and the resulting complex splits into two parts, each of which closes up into a ring with three nitrogen atoms and the simultaneous loss of nitrogen and water to form the intermediate product:

$$H-N\triangleleft\begin{matrix}N-N=O\\N-N=O\end{matrix}$$

which then gives off nitrous oxide and oxygen, leaving hydrazoic acid. J. Thiele obtained better results—in fact, almost a theoretical yield—by using an ethereal soln. of ethyl nitrite and sodium methoxide in well-cooled ethereal soln. R. Stollé used amyl nitrite in place of ethyl nitrite.

2. *The action of a compound containing a chain of two nitrogen atoms united to a negative atom or radicle* (e.g. *nitrous oxide,* N_2O) *upon a compound containing a single nitrogen atom united to positive atoms or radicles* (e.g. *ammonia,* NH_3). The type reaction is $N_2O+NH_3\rightarrow N_3H+H_2O$. W. Wislicenus could not make the acid by the direct union of these two compounds, but was able to make it quite readily from inorganic materials by the action of dry nitrous oxide upon sodamide between 150° and 250°:

$$\begin{matrix}N\\ \vdots\\ N\end{matrix}>O+\begin{matrix}H\\ \vdots\\ H\end{matrix}>N-Na\rightarrow H_2O+\begin{matrix}N\\ \vdots\\ N\end{matrix}>N-Na$$

Dry ammonia is passed over metallic sodium in a nickel boat between 250° and 350°, and sodamide, $NaNH_2$, is formed. In about six hours all the sodium will have been converted into amide, and the current of ammonia is replaced by one of nitrous oxide. This is continued at 190° for about 6 hrs. when ammonia is no longer evolved. The product of the reaction is a mixture of sodium hydroxide and sodium azide. This is dissolved in water, the soln. acidified with dil. sulphuric acid (1 : 1), and distilled. The first quarter of the distillation contains most of the hydrazoic acid. W. Wislicenus, and L. M. Dennis and A. W. Browne obtained hydrazoic acid in this way by the ammonolysis of nitrous oxide at high temp., and A. Joannis likewise by working at a low temp. in liquid ammonia. E. C. Franklin obtained sodium azide by allowing a mixture of sodium nitrate and amide to react with liquid ammonia warmed in a sealed tube; and A. W. Browne and F. Wilcoxon, by the action of sodium amide on the fused nitrate: $NaNO_3+3NaNH_2=NaN_3+3NaOH+NH_3$; a 65·7 per cent. yield was obtained at 175°—presumably the high temp. favours the decomposition of the azide. R. Stollé treated cyanamide or dicyanodiamide, or their derivatives, with nitrous oxide at a high temp. in the presence of a catalyst and a dehydrating agent; and distilled the resulting azido-compound with an acid to produce hydrazoic acid.

3. *The simultaneous oxidation of two compounds, one of which contains two nitrogen atoms and the other a single nitrogen atom, and both united to positive atoms or radicles.*—The type reaction: $H_2N.NH_2+NH_2OH+O_2\rightarrow HN_3+3H_2O$, is illustrated by S. M. Tanatar's method in which a hot soln. of mol. proportions of hydroxylamine and hydrazine in dil. sulphuric acid is oxidized by the slow addition of permanganates, bromine, red-lead, lead dioxide, hydrogen dioxide (yield about 26 per cent.), or chromic acid (yield about 29 per cent.). The hydrazoic acid is separated by distillation. L. M. Dennis and co-workers suggest a reversal of this method—the simultaneous reduction of two compounds, one of which contains a chain of two nitrogen atoms and the other a single nitrogen atom and both united to negative radicles—as a likely process for investigation.

4. *The oxidation of hydrazine sulphate by various oxidizing agents.*—The type reaction is symbolized: $3N_2H_4+5O\rightarrow 2HN_3+5H_2O$. A. W. Browne and co-workers made a special study of this process. The fact that ammonia is found among the products of the reaction has led to the inference that there is a side reaction: $2N_2H_4+O_2=N_3H+NH_3+2H_2O$; but F. Sommer has given a more probable explanation of the reaction; he considers that ammonia is the first

product of the oxidation of hydrazine; and if the oxidizing agent can convert this into nitrous acid, there will be a side-reaction between the nitrous acid and the hydrazine still unacted upon whereby hydrazoic acid is formed, and therefore the formation of hydrazoic acid by the oxidation of hydrazine is a special case of the first type of the methods of preparation here being described. The presence of hydrazoic acid is taken as evidence that nitrous acid was formed as an intermediate product. With *potassium persulphate* as oxidizing agent, A. W. Browne obtained a 40 per cent. yield of the acid; with *hydrogen dioxide* in dil. sulphuric acid, a 28 per cent. yield—the more acid the soln., the greater the yield of hydrazoic acid up to a soln. containing 5 grms. of hydrazine sulphate, 250 c.c. of water, and 100 c.c. of conc. sulphuric acid. *Ammonium metavanadate* at 80° gave a 13·5 per cent. yield; *potassium chlorate*, in the presence of dil. sulphuric acid, 22·4 per cent. of hydrazoic acid accompanied by 48·8 per cent. of ammonia; *potassium bromate*, 6·58 per cent. of hydrazoic acid along with 9·77 per cent. of ammonia; while *potassium iodate* gave no result—the last-named salt, however, does oxidize in the presence of silver sulphate. *Potassium permanganate* and *manganese dioxide*, as oxidizing agents gave respectively 3·2 and 2·3 per cent. of the acid. The production of hydrazoic acid during the electrolysis of hydrazine salts has been discussed in connection with hydrazine.

5. *The decomposition of a compound containing a chain of three or more nitrogen atoms.*—For example, M. Freund and A. Schander prepared hydrazoic acid by the action of alkalies on amidothionitrazole:

$$N\leqslant\begin{array}{l}N{-}N\\ S{-}\ddot{C}{-}NH_2\end{array}$$

and J. Thiele prepared it by the action of alkalies upon diazoguanidine salts, say the nitrate

$$\begin{array}{r}H{-}N\\ H_2{=}N\end{array}\!\geqslant C{-}H{<}\begin{array}{l}H\\ N{=}N{-}NO_3\end{array}$$

The aq. soln. of the free acid can be obtained by distillation with sulphuric acid as indicated above; repeated fractional distillation furnishes a soln. containing 91 per cent. of hydrazoic acid. The remaining water must be removed by calcium chloride.

An aq. soln. of hydrazoic acid was prepared by the Deutsche Gasglühlicht-Auer Gesellschaft by adding oxalic acid and alcohol to a soln. of alkali azide, and removing the precipitate. L. M. Dennis and H. Isham prepared the anhydrous acid by slowly dropping dil. sulphuric acid (2:1) on to dry potassium azide warmed in a large flask, Fig. 54, while a current of air, freed from carbon dioxide and moisture, was passed through the system. The hydrazoic acid is carried by the stream of air through a U-tube with a 30-cm. layer of calcium chloride, and thence into a receiver cooled by liquid air where the hydrazoic acid is frozen to a white solid. To prevent waste, the receiver should be followed by a flask containing methyl alcohol, and fitted with a calcium chloride tube. The apparatus should be placed in a hood behind a screen of thick plate-glass because anhydrous hydrazoic acid is very liable to explode violently at room temp. The hands should be protected by heavy gloves, and the face by a mask with plate-glass goggles. For phosphorus pentoxide as a desiccating agent, *vide infra.*

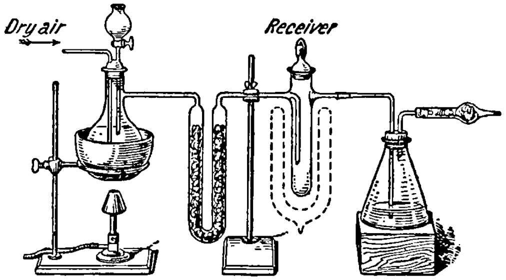


Fig. 54.—L. M. Dennis's Apparatus for Anhydrous Hydrazoic Acid.

The physical properties of hydrazoic acid.—Hydrazoic acid is a colourless, mobile, volatile liquid. According to L. M. Dennis and H. Isham, the liquid is heavier than water and possesses a high surface tension, and large vap. press. At ordinary temp., the liquid appears to be quite stable—a sample kept for 4 or 5 days showed no signs of decomposition. It may be shaken in smooth-walled vessels without danger of explosion. P. J. Kirkby and J. E. Marsh measured the quantity of electricity set free when hydrogen azide is exploded by the passage of an electric spark; they found that the number of ions set free is exceedingly small in comparison with the number of mols. decomposed in the explosion. The ratio was always less than 1 to 100,000, and this seems to indicate that dissociated atoms do not, in general, carry electrostatic charges. It is supposed that the formation of the ions is due to those impacts between the dissociated atoms which occur under specially favourable conditions, amongst which a relatively high velocity is probably the most important. Except under these circumstances, the combination of the dissociated atoms takes place without the production of ions. From experiments at different press. it was found that the hydrazoic acid could not be exploded when the press. was less than about 10 mm. In the case of pure hydrazoic acid this limiting press. would probably be smaller. The value of the limiting press. is much smaller than that obtained in previous experiments with electrolytic gas, for which 80 mm. was observed as the lower limit. After the explosion experiments, copper azoimide was found to be present in the gold-plated brass explosion vessel, and it is shown that this is probably formed in the actual explosion, the dissociated N_3-group being driven through the layer of gold into the brass as a consequence of the forces developed in the mol. disruption. T. Curtius and R. Radenhausen's attempts to determine the vapour density were frustrated by its instability—*i.e.* its explosiveness; but L. M. Dennis and H. Isham succeeded in showing that the vapour density corresponds with the formula HN_3. The liquid boils at 37°, and it furnishes a white solid on cooling. The solid melts at —87°. At the b.p., the liquid vaporizes mainly from the surface, only very small gas bubbles rise through the liquid. It is not decomposed when boiled. According to M. Berthelot and C. Matignon, the heat of formation in aq. soln. is $(3N,H,Aq.)=-61\cdot6$ Cals.; $N_4H_4+Aq.=N_3H.NH_{3soln.}-32\cdot3$ Cals.; $N_4+H_4=N_3H.NH_{3cryst.}-25\cdot3$ Cals. Hydrazoic acid is the most endothermic compound of the nitrogen hydrides. The heat of soln., at 11°, is —7·08 Cals.; the heat of neutralization by baryta, 10·0 Cals., and by ammonia, 8·2 Cals. The heat of combustion at constant vol. is 163·8 Cals., and at constant press., 163·3 Cals. J. C. Philip found that while the increment of at. refraction for an atom of bromine is 8·93, that for the triazo-group is 8·91; and for the at. dispersion, the increment due to bromine 0·35, and to the triazo-group, 0·36. W. Ostwald said that the electrical conductivity of aq. soln. of the acid shows it to be stronger than acetic acid. A. Hantzsch found that the conductivity increases so much with rise of temp. that at 25° the acid is almost as strong as acetic acid, and at 0°, it is rather weaker. C. A. West obtained for the mol. conductivity, μ, for a dilution $v=10$, $\mu=5\cdot38$; for $v=100$, $\mu=15\cdot98$; and for $v=1000$, $\mu=45\cdot97$. The ionization constant thus ranges from $0\cdot0_4166$ to $0\cdot0_4198$; and the value deduced from the inversion of cane-sugar is $0\cdot0_4186$. He therefore inferred that the strength of the acid is somewhat greater than that of acetic acid, and approximately one-seventieth the strength of hydrochloric acid. E. Oliveri-Mandalà gave $0\cdot8\times10^{-5}$ for the ionization constant of the acid for $v=40$ at 0°; $0\cdot9\times10^{-5}$ at 10°; and $1\cdot2\times10^{-5}$ at 20°; and A. Hantzsch gave for $v=64-256$ at 0°, $1\cdot0\times10^{-5}$, and $1\cdot9\times10^{-5}$ at 25°. J. C. Philip, and W. G. Schaposchnikoff studied this question. M. le Blanc found the decomposition potential to be 1·29 volts. E. C. Szarvasy, and A. W. Browne and G. E. F. Lundell showed that during the electrolysis of hydrazoic acid rather a smaller vol. of nitrogen is liberated at the anode than corresponds with theory, and this was attributed to a polymerization of the nitrogen, but A. Peratoner and G. Oddo said that it is more likely to be caused by secondary reactions. According to A. W. Browne and

G. E. F. Lundell, purified hydrazoic acid offers a very high resistance to the electric current and has a sp. conductivity approximately equal to that of pure ammonia. On dissolving potassium azide in the anhydrous acid, the conductivity is greatly increased, and when such a soln. is electrolyzed, at —78°, nitrogen and hydrogen are evolved in a ratio which is approximately 3 : 1, but somewhat less under certain conditions. Ammonia is formed during the electrolysis, but hydrazine is not produced. Where the apparatus was not shattered, mercury was attacked at the anode, indicating that active nitrogen is there produced. This subject was studied by F. L. Usher and R. Venkateswaran. L. M. Dennis and H. Isham electrolyzed hydrazoic acid with a zinc anode—*vide infra*, zinc azide. L. Birckenbach and K. Kellermann compared the decomposition potential of the potassium salts of the halogens and what he called the pseudohalogens, and found that they could be arranged in the sequence: TeCy, SeCy, I, SCy, Cy, Br, N_3, Cl, OCy, and F, in which there is no direct relationship between affinity and at. or mol. wt.

The chemical properties of hydrazoic acid.—The resemblances between hydrazoic acid and the halogen hydracids has led some to infer that the triazo-group, N_3, bears a strong family resemblance to the halogens. J. C. Philip found the physical properties—light refraction, light dispersion, boiling point, electrical conductivity, etc.—of the organic triazo-derivatives and the corresponding halogen derivatives to be comparable. In illustration,

	Acetic	Iodo-	Triazo-	Bromo-	Chloroacetic acids.
Ionization constant ($\times 10^{-4}$)	0·01	7·5	9·3	13·8	15·8

In view of the resemblances between the triazo-group and the halogens—*e.g.* Cl—Cl, N_3—Cl, etc.—attempts have been made to prepare a hexatomic nitrogen, N_3—N_3, by linking together two triazo-groups, but with no success other than the naming of the hypothetical $(N_3)_6$, *nitrine*, by L. M. Dennis and A. W. Browne. The analogy between ammonia and water, suggested by E. C. Franklin, led A. W. Browne and T. W. B. Welsh, and H. Goldberg to seek for analogies between the azides and the peroxides.

Work with hydrazoic acid is dangerous because of its poisonous and explosive qualities. The acid has an unpleasant, penetrating odour. According to L. Smith and C. G. L. Wolf, and M. O. Forster, the vapour is extremely poisonous, and, when inhaled in even trifling quantities, causes distressing headache; it is in fact a powerful protoplasmic poison, its activity in this direction being comparable with that of hydrocyanic acid. Its effect on the blood spectrum is immediate and pronounced. O. Löw reported that subcutaneous injections of the sodium salt in certain mammals produce spasms, and symptoms of heart and lung paralysis. The fumes from even dil. aq. soln. were found by T. Curtius and J. Rissom to produce giddiness, headache, and inflammation of the nasal passages. The aq. soln. makes painful burns on the skin. The salts of the alkali metals may be handled without risk of explosion, but those of the heavy metals are dangerously explosive. W. T. Cooke found that hydrazoic acid is partly reduced by sodium amalgam—nascent *hydrogen*—forming ammonia and a little hydrazine; zinc and sulphuric or hydrochloric acid also reduce the acid. Only when the hydrazine is removed, in an insoluble form, from the reacting system, is a considerable quantity of hydrazine produced. It is supposed that the reaction is: $HN_3+3H_2=NH_3+N_2H_4$, and the hydrazine is immediately reduced. No evidence of the formation of *triimide*, or *triazotrihydride*,

$$\begin{matrix} H{-}N \\ H{-}N \end{matrix}\!\triangleright N{-}H$$

was obtained. E. Briner and P. Winkler, and J. Piccard and E. Thomas, studied the reduction of hydrazoic acid. If hydrazine, free from hydrate, be treated with sodium the metal is at first coated with a dark blue layer of, presumably, **sodium hydrazonium** analogous to sodammonium; with the continued action, the liquid becomes yellow. Hydrazoic acid is miscible with *water* or *alcohol*, in all proportions at ordinary temp., without forming any definite hydrate. The aq. soln. is not affected when boiled with water alone. When the aq. soln. is distilled, it seems to form a soln. with a constant b.p. The aq. soln. colours blue litmus red; and in most of its properties its behaviour is comparable with that of hydrochloric acid. As in the case of hydrochloric acid, hydrazoic acid when brought near a bottle of ammonia, furnishes a white cloud of the ammonium salt. Aq. soln.—even very dil.—keep an indefinitely long time in stoppered bottles; but in conc. soln., the acid is dangerously explosive. The acid, said J. Martin, is oxidized in acidic soln. in the presence of ceric sulphate.

F. Raschig found that hydrogen azide exhibits some basic properties, for, with *sodium hypochlorite* and hydrazoic acid, or sodium hypochlorite and sodium azide acidified with acetic or boric acid a highly explosive gas, **chlorazide,** N_3Cl, is formed. This gas smells like hypochlorous acid, and is decomposed by an aq. soln. of sodium hydroxide: $N_3Cl+2NaOH=NaN_3+NaOCl+H_2O$. Chlorazide is slightly soluble in water, forming a yellow soln., and it explodes with extraordinary violence when brought into contact with a flame or glowing splinter, and sometimes spontaneously with the production of a blue flame. K. Gleu found that chlorazide is decomposed at 400° and 2 mm. press. without explosion; the decomposition is accompanied by a red glow, which excites the fluorescence of the glass. The spectrum shows four groups of bands in the red which are attributed to a molecule containing both nitrogen and chlorine; in the ultra-violet, there are continuous bands with maxima at 3060 and 2570 A. This spectrum is not shown by decomposing chlorine dioxide. The addition of hydrogen produces an intense white glow identical with the α-band of ammonia in the visible region. This is attributed to a molecule containing both nitrogen and hydrogen. No nitrogen bands are shown. D. A. Spencer passed dried *bromine* vapour diluted with nitrogen over dried silver or sodium azide, and condensed the product in vessels cooled by a freezing mixture. Violent explosions sometimes occurred. A capillary tube served as a connecting link between the reaction tube and the condensing vessels so as to localize any explosion which might occur. The condensate was fractionated in a current of nitrogen, and **bromazide,** N_3Br, was obtained as a mobile, very volatile, orange-red liquid: $NaN_3+Br_2=NaBr+N_3Br$. Bromazide was also obtained by the interaction of sodium or silver azide and bromine dissolved in ether, benzene, or ligröin. The bromide attacks the solvent to some extent, and it is not possible to separate the solvent from the bromazide. Bromazide is much more volatile than the iodoazide, and likewise much more sensitive to water. A trace of moisture immediately hydrolyzes the compound. The liquid bromazide freezes to a dark red solid at about −45°. The pungent vapour has toxicological properties similar to hydrazoic acid, causing giddiness, headache, and a slackening of the muscles when inhaled. Traces of the vapour irritate the eyes and cause a slight difficulty in breathing, due apparently to congestion of the nasal mucous membrane. Solid, liquid, and vapour are as sensitive to shock as iodoazoimide, the explosion (often apparently spontaneous) being accompanied by a flash of livid blue light. The liquid explodes in contact with phosphorus, arsenic, sodium, and silver foil, but the vapour, when diluted with nitrogen and passed over silver leaf or sodium, gives a film of the corresponding azide and bromide. The liquid is apparently miscible in all proportions with ether, but is less soluble in benzene or ligröin. These soln. are stable for a few hours in the dark, but, when concentrated, are liable to explode on shaking, and on standing gradually decompose, giving nitrogen and bromine, the latter attacking the solvent. When passed into water, bromoazoimide hydrolyzes instantaneously, giving a mixture of hydrazoic and hypobromous acids, and the soln., on standing, evolves nitrogen by interaction of these acids. A trace of ammonium salt is formed during the hydrolysis. When bromoazoimide is passed into potassium iodide soln., iodine is liberated equivalent to the hypobromous acid produced and potassium azide is obtained: $N_3Br+2KI=KN_3+KBr+I_2$. According to A. Hantzsch, silver azide in a cold ethereal soln. of *iodine* gives a yellow explosive and unstable **iodoazide,** $N_3Ag+I_2=N_3I+AgI$. The freshly prepared, aq. soln. of iodoazide is neutral toward litmus and starch, but the soln. soon hydrolyzes into hydrazoic and hypoiodous acids. A trace of ammonia is obtained during the hydrolysis. In non-aqueous solvents, the compound slowly decomposes into iodine and nitrogen. F. Raschig showed that hydrazoic acid is oxidized by a slight excess of iodine and a crystal of sodium thiosulphate, whereby nitrogen is evolved. The gas can be measured and the reaction used analytically. No gas is evolved with a mixture of sodium thiosulphate and iodine, or with hydrazoic acid and iodine. F. Raschig considers that an intermediate compound, $NaIS_2O_3$, is formed: $Na_2S_2O_3+I_2=NaI+NaIS_2O_3$, the intermediate compound readily gives up its iodine to sodium azide or to sodium thiosulphate, forming in the latter case sodium tetrathionate, $Na_2S_2O_3+NaIS_2O_3=Na_2S_4O_6+NaI$. Hence the catalyst $Na_2S_2O_3$ takes up iodine, giving it up to the azide or condenses to tetrathionate. Free mineral acids hinder the reaction, and since sulphuric acid is liberated as a by-product, it is advisable to add sodium acetate. Because of this effect of acids, it is always advisable, too, to keep adding sodium thiosulphate to the soln., and this is best effected by using a crystal about the size of a pea, which takes sufficiently long to dissolve. Hydrazoic acid seems to be the only substance which, whilst unattacked by iodine alone, is oxidized by iodine in the presence of sodium thiosulphate. Bromine water and thiosulphate have the same effect, owing, no doubt, to the formation of $NaBrS_2O_3$. The only other iodine carrier which has been discovered among sulphur compounds is a sulphide. A crystal of sodium sulphide has the same effect, but some sulphur is at the same time set free.

The aq. soln. of hydrazoic acid is slowly decomposed by boiling with dil. *mineral acids.* A. W. Browne and A. B. Hoel found that *hydrochloric acid* heated with a little hydrazoic acid furnishes chlorine: $N_3H+2HCl=NH_3+Cl_2+N_2$; and with *hydriodic acid,* iodine: $N_3H+2HI=NH_3+N_2+I_2$. Just as A. W. Browne and O. R. Overmann found that sulphuric acid deammoniates nitrogen compounds in Kjeldahl's reaction, so sulphuric acid can dehydrazinize the azides, for H. Isham found ammonia and hydrogen in the products obtained by passing dry azomide into conc. sulphuric acid; and H. S. Bennett, by mixing sulphuric acid and an ethereal soln. of azomide. Hydrazoic acid is only slightly oxidized by *potassium chlorate;* while *potassium persulphate* has a marked oxidizing action. W. T. Cooke found *sodium sulphide* reduces hydrazoic acid to ammonia and small quantities of hydrazine.

A. C. Vournazos prepared some complex azides. Anhydrous zinc chloride and sodium azide react in methyl alcohol soln., forming **sodium zinc chloroazide,** $Na[ZnCl_2N_3]$; while with zinc nitrate in aq. soln., **zinc hydroxyazide,** $ZnN_3(OH)$, is formed. Zinc nitrate acts on sodium zinc chloroazide, forming **sodium zinc nitratochloroazide,** $[Zn(NO_3)_2.4ZnCl_2N_3]Na_4.6H_2O$. Similarly, **sodium zinc bromoazide,** $Na[ZnBr_2N_3]$, and **sodium zinc iodoazide,** $Na[ZnI_2N_3]$, were obtained. The iodo-compound reacts with silver iodide to form sodium **silver zinc iodoazide,** $Na(ZnI_2N_3)—AgI—Na(ZnI_2N_3)$; and with lead iodide, **sodium lead zinc iodoazide,** $PbI_2\{(ZnI_2N_3)Na\}_4$. Compounds of sodium zinc azide with hydrocyanic, formic, and acetic acids were also prepared. The action of sodium azide on arsenic tribromide gives **arsenic azide,** $As(N_3)_6$, which reacts with sodium azide, forming the complex **sodium arsenic bromoazide,** $Na_8[AsBr_3(N_3)_8]$. When bismuth iodide is treated with an equimolar part of sodium azide, the reaction is that symbolized: $2BiI_3+2NaN_3+H_2O=BiOI+BiI_3+2HN_3+2NaI$; and with twice this proportion of sodium azide: $BiI_3+2NaN_3+H_2O=BiOI+2NaI+2HN_3$. It is thought that an unstable **bismuth iododiazide,** $BiI(N_3)_2$, is formed and immediately hydrolyzed.

F. Ephraim and H. Piotrowsky obtained evidence of the formation of **hydrazine hydrosulphide,** $N_2H_4.H_2S$, by the action of anhydrous hydrazine on *hydrogen sulphide* (*q.v.*); and there is a possibility that a hydrazinosulphinate (*q.v.*) is formed by the action of hydrazine on thionyl chloride (*q.v.*). F. Raschig said that the reduction of hydrazoic acid with *sodium hydrosulphite* may be represented: $NaHSO_3+NaN_3+H_2O=N_2+NaOH+NH_2.NaSO_3$, together with the subsidiary reaction: $2NaHSO_3+NaN_3+H_2O=Na_2S_2O_6+NH_3+NaOH+N_2$. Just as a secondary amine like diethylamine, $N(C_2H_5)_2N$, reacts with *carbon disulphide* to form the compound $N(C_2H_5)_2.CS.SH$, so F. Sommer found that hydrazoic acid, in the form of an aq. soln. of its sodium salt, reacts with carbon disulphide, at 45°–50°, forming **sodium azidodithiocarbonate,** $N_3.CS.SNa.4H_2O$, in colourless, explosive crystals. The anhydrous salt was also obtained. A. W. Browne and co-workers prepared the dihydrate, as well as **lithium azidodithiocarbonate,** $LiS.CS.N_3.H_2O$; and F. Sommer, **potassium azidodithiocarbonate.** The reactions were also studied by A. W. Browne and A. B. Hoel. They found that potassium azide reacts with iodine in the presence of carbon disulphide, with the formation of potassium iodide and the liberation of nitrogen. The first stage in this reaction consists in the formation of potassium azidodithiocarbonate, $KS.CS.N_3$, by interaction of potassium azide and carbon disulphide, as expressed by the equation $KN_3+CS_2=KS.CS.N_3$. This reaction is irreversible, consequently there is no regeneration of carbon disulphide after it has once reacted. The second stage consists in the reaction between potassium azidodithiocarbonate with iodine, which results in the precipitation of azidocarbon disulphide, $S_2(CS.N_3)_2$, according to the equation $2KS.CS.N_3+2I=S_2(CS.N_3)_2+2KI$. The halogenoid substance azidocarbon disulphide liberates triatomic nitrogen from potassium azide, with resultant evolution of ordinary nitrogen, as shown by the equations $2KN_3+S_2(CS.N_3)_2=2KS.CS.N_3+2N_3$; $2N_3=3N_2$. Combination of these equations with the preceding one leads to the simple expression of the final result obtained when carbon disulphide, potassium azidodithiocarbonate, or azidocarbon disulphide, in relatively small amount, is brought into contact with a soln. containing potassium azide and iodine. These results have been confirmed by iodometric and nitrometric determinations: $2KN_3+2I=2KI+3N_2$. A. W. Browne and co-workers prepared **rubidium azidodithiocarbonate,** $RbS.CS.N_3$, and **cæsium azidodithiocarbonate,** $CsS.CS.N_3$, by the union of carbon disulphide with the alkali azides. The solubilities of the alkali salts decrease in the order Li, Cs, Rb, Na; they are insoluble in carbon disulphide, chloroform, carbon tetrachloride, and benzene. They tend to decompose at the ordinary temp.: $MS.CSN_3=MS.CN+S+N_2$. The violence of the explosion on detonation varies directly as the atomic weight of M, except that the lithium salt is more explosive than the sodium salts. The explosion liberates a gas with a sulphurous odour, leaving a viscous, yellow residue, probably a polymeride of thiocyanogen. The rubidium and cæsium salts are very photosensitive; on alternate illumination and confinement in a dark space, "photolysis" occurs and the salt decomposes. The colour change on illumination is ascribed to free metal atoms held *in situ* in the crystal lattice, their valency electrons having been restored by some photo-process. The salts of the heavy metals—*barium, silver, copper, mercury* (*ic and ous*), *lead, thallium, cadmium, bismuth, and zinc*—are precipitable from soln. of the sodium salt. *Ferric salts* oxidize the compound to *azidothiocarbonyl disulphide,* $(N_3.CS)_2S_2$; many of the azidodithiocarbonates, like the xanthates, are soluble in the ordinary organic solvents, and they do not always show the colour of the metal base. Most of the salts are very explosive. By treating the sodium salt with hydrochloric acid, free **azidodithiocarbonic acid,** $HS.CS.N_3$, is formed. According to G. B. L. Smith, and F. Wilcoxon, this acid has been prepared by the treatment of conc. soln. of the sodium salt with concentrated hydrochloric acid. It is a white or very pale yellow, crystalline solid; it crystallizes in the monoclinic system, has a strong double refraction, and is readily soluble in nonaqueous solvents. It has the characteristic properties of a strong acid, and its strength approaches that of hydrochloric acid. It is easily oxidized by various oxidizing agents, yielding free **azidodithiocarbonate,** $(S.CS.N_3)_2$. In the solid form, the acid is very sensitive to both shock and to heat. It undergoes spontaneous decomposition at the odinary temp., in keeping with the laws of unimolecular change. In the dry state, this reaction is catalyzed by an intermediate product or by the thiocyanic acid formed, but not in aq. soln. The decomposition may be represented by the equation $HS.CS.N_3=HSCN+S+N_2$. The solid product formed consists of polymerized thiocyanic acid and free sulphur. **Ammonium azidodithiocarbonate,** NH_4SCSN_3, was also prepared.

H. E. Rigger studied the f.p. of the system containing **hydrazine** and hydrazoic acid, and obtained as a white, crystalline compound $N_3H.2N_2H_4$, or $N_2H_5.N_3.N_2H_4$, or $N(N_2H_3)_3$, *nitrogen trihydrazinide.* According to J. Thiele, and E. Oliveri-Mandalà, hydrazoic acid reacts with *nitrous acid:* $N_3H+HNO_2=N_2+N_2O+H_2O$. F. Sommer and H. Pincas confirmed this conclusion by adding acetic acid to an eq. mixture of barium nitrate and sodium azide. The reaction can be used to detect nitric acid in the presence of nitrous acid and of nitrous acid alone. Even in a 0·0001*N*-soln., the nitrous acid is destroyed by sodium azide; while nitric acid is not affected by the hydrazoic acid. The reaction was also studied by E. Oliveri-Mandalà, and E. A. Werner. P. J. Kirkby and J. E. Marsh showed that hydrogen azide is readily absorbed by *phosphoric acid,* but no change in vol. occurs when fresh *phosphoric oxide* is used as a desiccating agent. According to E. Oliveri-Mandalà, and T. Passalacqua, when *cyanogen* is passed into a 40 per cent. soln. of hydrazoic acid, **cyanotetrazole,** C_2N_5H, or $C_2N_2.N_3H$, is formed. It melts at 99°, and turns red at 70°. It yields ammonia quantitatively when boiled with potash-lye. It forms **barium cyanotetrazole,** $Ba(C_2N_5)_2Ba.3\frac{1}{2}H_2O$; and **silver cyanotetrazole,** AgC_2N_5. E. Oliveri-Mandalà and F. Noto obtained ethylcarbamazide, $NHC_2H_5.CO.N_3$, from *ethylcarbimide* and hydrazoic acid; **phenylcarbamazide,** $NHC_6H_5.CO.N_3$, from *phenylcarbimide* and hydrazoic acid; and **phenylthiotetrazoline** and a substance, $C_7H_7N_7S$, from *phenylthiocarbimide* and hydrazoic acid respectively at 40° and 60°–70°.

According to T. Curtius and A. Darapsky, a 7 per cent. soln. of the acid acts upon the metals, iron, zinc, cadmium, copper, aluminium, and magnesium, with a brisk evolution of hydrogen and ammonia; a more conc. soln. appears to attack even gold and silver. J. W. Turrentine and R. L. Moore found that when a 2 per cent. soln. of azide is added to finely-divided *copper,* nitrogen is slowly evolved, ammonia is produced, and the metal is gradually changed into cupric azide. The reaction is represented by the equation: $Cu+4N_3H=CuN_6+NH_4N_3+N_2$. F. Raschig found that hydrazoic acid in alkaline soln. is reduced by *aluminium* to hydrazine and ammonia: $HN_3+H_2=N_2+NH_3$; and $HN_3+3H_2=NH_3+N_2H_4$. O. Löw showed that *platinum* black acts catalytically on hydrazoic acid, forming ammonia; and, according to E. Oliveri-Mandalà, the gas liberated during the catalysis of hydrazoic acid by platinum-black consists solely of nitrogen, and estimations of the amounts of this gas and of ammonia formed from a certain quantity of the hydrazoic acid show that the reaction may be expressed by the equation: $3N_3H=4N_2+NH_3$. This final result is probably obtained by way of the intermediate stages $3N_3H=3NH+3N_2$, $3NH=(NH)_3$, and $(NH)_3=NH_3+N_2$. If the catalysis occurs under ordinary conditions, the constant for a unimolecular reaction diminishes very considerably as the reaction proceeds, but if the liquid is stirred to render it uniform and to facilitate the liberation of the gas in the soln., the value of the constant undergoes only very slight alteration. Hydrogen occluded in platinum foil decomposes hydrazoic acid three times as rapidly as does oxygen similarly occluded. Colloidal platinum exhibits only feeble activity in the decomposition of hydrazoic acid in aq. soln., and this result is shown to be due to a "poisoning" of the platinum by the hydrazoic acid; the alkali salts of the latter exert a similar poisoning action on colloidal platinum. J. W. Turrentine and R. L. Moore found that when a 2 per cent. soln. of hydrazoic acid is added to yellow *cuprous oxide,* the latter is rapidly changed to a flocculent substance of darker colour. This substance is an unstable nitrogenous compound (probably cuprous azide), which in contact with excess of hydrazoic acid undergoes gradual transformation into cupric azide. In this reaction the hydrazoic acid suffers reduction with formation of ammonia and nitrogen. The following equation represents this change qualitatively: $Cu_2O+5N_3H=2CuN_6+H_2O+NH_3+N_2$. The transformation takes place more readily in presence of sulphuric acid, and this is probably due to the protective coating of cupric azide being constantly removed by soln. in the acid. The oxidation of cuprous azide by hydrazoic acid is greatly accelerated by light. Again, when *cuprous chloride* is treated with a dil. soln. of hydrazoic acid, it loses its white, crystalline form and becomes bulky, yellow, and flocculent. On addition of hydrochloric acid, the substance resumes its original crystalline form. If cuprous chloride is treated repeatedly with fresh portions of the hydrazoic acid, a substance is produced which resembles that obtained by the interaction of cuprous oxide and hydrazoic acid. This compound is free from chlorine, and appears to be cuprous azide. F. Sommer and H. Pincas found that quadrivalent *cerium salts*—ceric ammonium nitrate, ceric ammonium sulphate, or ceric sulphate—completely oxidize hydrazoic acid in neutral or acid soln. even when very dil.: $2N_3H+2CeO_2=3N_2+Ce_2O_3+H_2O$. It is suggested the reaction can be used analytically by measuring the vol. of the liberated hydrogen provided free hydrochloric acid or chlorides be absent. F. Raschig found that acidic reducing agents like *stannous chloride* and hydriodic acid reduce hydrazoic acid to ammonia and nitrogen. According to A. W. Browne and A. B. Hoel, potassium manganate is formed by the interaction of a heated mixture of potassium azide and *manganese dioxide.* The reaction is vigorous; but hydrazoic acid alone has only a slight action on manganese dioxide. L. M. Dennis and A. W. Browne found that *potassium permanganate* vigorously oxidizes hydrazoic acid to water and nitrogen; some oxygen is liberated at the same time. The action seems to involve a pair of consecutive reactions: $2KMnO_4+10NH_3+3H_2SO_4 \rightarrow K_2SO_4+2MnSO_4+15N_2$ and $2KMnO_4+6NH_3+3H_2SO_4 \rightarrow K_2SO_4+2MnSO_4+6H_2O+O_2+9N_2$, for when the hydrazoic acid is in excess a given amount of permanganate will react with more hydrazoic acid than when the permanganate is in excess. F. Raschig found that hydrazoic acid is not attacked by potassium permanganate in neutral or alkaline soln., but in sulphuric acid soln. it is slowly oxidized to **hypoazoic acid,** N_3OH, thus: $N_3H+O=N_3OH$. In addition, a portion is probably oxidized to triatomic nitrogen which then decomposes. yielding ordinary nitrogen molecules. Hypoazoic acid, N_3OH, resembles hypochlorous acid in many of its properties. It decomposes, yielding oxygen and probably hydrazoic acid. If hydrazoic acid be oxidized in sulphuric acid or boric acid soln. in the presence of sodium nitride, nitric acid is produced in two stages. The two intermediate products are:

$${}^{N}_{\ddot{N}}\!>\!N\!\leqslant^{OH}_{O}$$

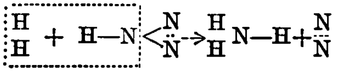
$${}^{N}_{\ddot{N}}\!>\!N(OH)\!<^{O}_{\dot{O}}$$

which, losing nitrogen, forms nitric acid. J. Piccard and E. Thomas found that a soln. of **chromous chloride** in acidic soln. reduced hydrazoic acid: $N_3H+H_2=NH_3+N_2$. Hydrazoic acid has only a slight action on *ferric oxide,* but W. T. Cooke found that *ferrous hydroxide* reduces hydrazoic acid, forming ammonia and a very small proportion of hydrazine. For the action of *ferrous and ferric salt* soln., *vide infra.*

The constitution of hydrazoic acid.—The vapour density and analyses both agree that the formula of hydrazoic acid is HN_3. The chief circumstantial evidence in support of the closed ring formula

$$H{-}N\!<^{N}_{N}$$

is that it agrees (i) with the formation of hydrazoic acid from sodamide and nitrous oxide; (ii) with the action of hydrogen on thallium azide which results in the formation of nitrogen and ammonia as shown by L. M. Dennis and M. Doan:

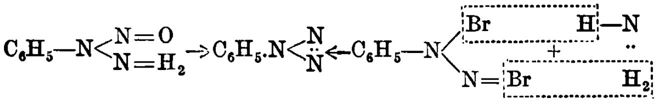


$$\boxed{\begin{matrix}H\\H\end{matrix} + H—N}\!<\!\begin{matrix}N\\ \ddot{N}\end{matrix} \rightarrow \begin{matrix}H\\H\end{matrix}N—H+\begin{matrix}N\\ \vdots\\ N\end{matrix}$$

(iii) with the formation of the potassium salt by the hydrolysis of phenyl azide as indicated above. This suggests that the N_3-group has the same structure in both compounds; and the structure of phenyl azide is assumed to be:

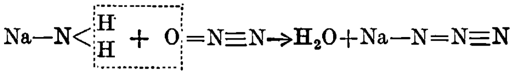
$$C_6H_5—N\!<\!\begin{matrix}N\\ \ddot{N}\end{matrix}$$

as a result of the work of E. Fischer, who showed that the formation of phenyl azide by warming phenylnitrosohydrazine, $C_6H_5.N(NO)NH_2$, with water; and the action of ammonia on diazobenzeneperbromide, $C_6H_5.NBr.NBr_2$, suggest a 3-ring formula for phenyl azide:



$$C_6H_5—N\!<\!\begin{matrix}N=O\\N=H_2\end{matrix} \rightarrow C_6H_5.N\!<\!\begin{matrix}N\\ \ddot{N}\end{matrix} \leftarrow C_6H_5—N\!\begin{matrix}\diagup \boxed{Br \quad H}—N \\ + \quad \ddot{} \\ \diagdown N=\boxed{Br \quad H_2}\end{matrix}$$

E. Oliveri-Mandalà and F. Noto favoured the ring hypothesis; but the experimental evidence is not so conclusive as to discountenance other interpretations. Metals below magnesium in the electrochemical series reduce hydrazoic acid to ammonia, and maybe to hydrazine and free nitrogen; no hydrogen is evolved, *e.g.* $Cu+3HN_3=CuN_6+N_2+NH_3$; with nitric acid, it will be remembered that $3Cu+8HNO_3=3Cu(NO_3)_2+2NO+4H_2O$. With some of the oxidizable non-metals, the acid is reduced, forming ammonia and nitrogen, thus: $H_2S+HN_3=S+N_2+NH_3$; with nitric acid, $3H_2S+2HNO_3=3S+2NO+4H_2O$; and with metals lying near the end of the electrochemical series, the acid is reduced, forming ammonia and nitrogen: $Pt+2HN_3+4HCl=PtCl_4+2N_2+2H_3N$—with nitric acid under similar conditions: $3Pt+4HNO_3+12HCl=3PtCl_4+4NO+8H_2O$. If two compounds behave in a similar manner, it is often assumed that they have an analogous structure; hence, argued J. W. Turrentine, if nitric acid has the structure $HO—N\equiv O_2$, with a quinquevalent nitrogen atom as nucleus united with two bivalent oxygen atoms, then, hydrazoic acid might be expected to contain a quinquevalent nitrogen atom united with nitrogen, of $H—N=N\equiv N$. He accordingly preferred the alternative term *hydronitric acid* for hydrazoic acid. This view agrees with some reactions in organic chemistry studied by J. Thiele in 1911; and who explained its formation from nitrous oxide and sodamide by assuming that nitrous oxide has the composition $O=N\equiv N$, and, accordingly, he wrote:



$$Na—N\!<\!\boxed{\begin{matrix}H\\H\end{matrix} + O}=N\equiv N \rightarrow H_2O+Na—N=N\equiv N$$

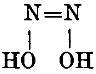
J. W. Turrentine also favoured J. Thiele's hypothesis, and he regarded it as an ammoniated nitrogen nitride in the ammonia system in the same sense that nitric acid is a hydrated nitrogen oxide in the water system, and hence E. C. Franklin called hydrazoic acid *ammononitric acid.* A. W. Browne and co-workers regarded the azides as *pernitrides* analogous to the peroxides when nitric and nitrous acids are intermediate in composition and character between hydrogen pernitride (hydrazoic acid) and hydrogen dioxide. A. W. Browne and F. Wilcoxon said that hydrazoic acid is more closely related to nitrous acid than to nitric acid. Thus, iodine is not liberated by adding one per cent. soln. of nitric acid to hydriodic acid, but it is readily liberated by one per cent. soln. of nitrous or hydrazoic acid. The probable structural similarity of nitrous and hydrazoic acids is indicated by the many methods of preparing hydrazoic acid from nitrous acid or its derivatives. H. E. Armstrong examined the mol. refraction of hydrazoic acid and phenyl azide, but found the evidence did not decide in favour of either the 3-ring formula or the dinitrilic formula $=N-NH-N=$.

D. I. Mendeléeff argued that just as primary ammonium mesonitrate, $(NH_4O)(HO)_2NO$, is supposed to furnish nitrous oxide by the loss of three mols. of water, so may secondary ammonium mesonitrate, $(NH_4O)_2(HO)NO$, furnish hydrazoic acid by the loss of four mols. of water. This would make hydrazoic acid the nitrile of mesonitric acid :

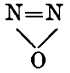
$$\begin{matrix}N\\[-6pt]\cdot\\[-6pt]N\end{matrix}\!\geqslant N-H$$

in the same way that hydrogen cyanide, $H-C=N$, can be regarded as the nitrile of ammonium formate, obtained by the loss of 2 mols. of water. Ammonium azide can be derived from tertiary ammonium mesonitrate, $(NH_4O)_3NO$, by the loss of 4 mols. of water. D. I. Mendeléeff then predicted that the more salient properties of the cyanides (nitriles) would characterize the azides, but subsequent events did not confirm these whimsical speculations. A. W. Browne and F. Wilcoxon add that hydrazoic acid can also be regarded as the nitrile of primary ammonium hyponitrite, $NH_4O.N:N.OH$.

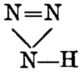
The following graphic formulæ show a kind of relationship between hydrazoic acid, nitrous oxide, and hyponitrous acid :



Hyponitrous acid.



Nitrous oxide.



Hydrazoic acid.

where nitrous oxide appears as if it were the anhydride of hyponitrous acid, and hydrazoic acid as *nitrous imide.* According to W. Schlenk and T. Weichselfelder, when hydrazine is mixed with methyl alcohol, heat is developed, and, on cooling with solid carbon dioxide, a mass of colourless needles is obtained. The mixture has no definite b.p., however, the affinity of hydrazine for alcohol being much smaller than the affinity for water. Hydrazine methylate, $[NH_2.NH_3]OMe$, is isomeric with methylhydrazine hydrate, $[NH_2.NH_2Me]OH$. M. L. Huggins made estimates of the interatomic distances of the atoms in the molecules of the potassium and sodium azides.

Some analytical reactions of hydrazoic acid.—When a ferric chloride soln. or a soln. of iron-alum is mixed with sodium azide ; or when a soln. of ferrous ammonium sulphate is shaken in air with sodium azide, a blood-red coloration is developed. The colour disappears when the liquid is boiled, and ferric hydroxide precipitates, the colour also disappears on standing owing to the separation of a *basic ferric azide—vide supra.* L. M. Dennis and A. W. Browne say that one part by weight of hydrazoic acid per 100,000 parts of water will give a distinct coloration, and hence, T. Curtius and J. Rissom consider this to be a *characteristische Reaktion auf Stickstoffwasserstoff.* The colour persists an indefinitely long time if the ferric salt be in excess—probably because the hydrolysis of the ferric azide is in this way prevented. The red coloration is remarkably like that produced by ferric thiocyanate, but dilute mineral acids, say hydrochloric acid, discharge the colour of the azide, but scarcely affect the colour of the thiocyanate. Mercuric chloride discharges the colour of ferric thiocyanate more readily than it does that of ferric azide. L. M. Dennis recommends the determination of hydrazoic acid and its soluble salts by precipitation as silver azide, *q.v.*, from neutral or acetic acid soln. by the addition of silver nitrate. The precipitate is converted into silver chloride for weighing.

§ 29. The Azides, Azoimides, Trinitrides, Hydrazoates, or Pernitrides

T. Curtius[1] prepared **hydrazine azide,** $N_2H_4.HN_3$, or H_5N_5, by treating ammonium azide with hydrazine hydrate, or by neutralizing hydrazoic acid with hydrazine hydrate. If a very conc. soln. of hydrazoic acid be treated with hydrazine hydrate until litmus is coloured blue, and the soln. is evaporated over sulphuric acid, or potash, the same salt is formed, and not $N_2H_4.2HN_3$, as might be anticipated by analogies from the behaviour of hydrazine with other acids. Ammonium azide crystallizes in large anisotropic prisms which melt at about 50°. The salt is hygroscopic, and if exposed to air at ordinary temp., it gradually volatilizes—and more readily so in the vapour of water or alcohol. The salt is sparingly soluble in boiling alcohol, and the hot soln., on cooling, deposits tabular crystals. The crystals can be ignited in air, and they burn with a yellow flame and much fuming, without leaving any residue. When rapidly heated in air, say with a white-hot wire, the salt explodes violently; similar explosion occurs with a detonator. The moist salt is also explosive.

T. Curtius prepared **ammonium azide,** $NH_3.HN_3$, or $NH_4.N_3$, or N_4H_4, by passing ammonia gas into an alcoholic soln. of diazohippurylamide, and precipitating the product by the addition of ether. It is also formed from a mixed soln. of hydrazoic acid and ammonia. The salt can be crystallized from its aq. soln. in colourless plates, with habits bearing a formal resemblance to those of ammonium chloride. The crystals are not hygroscopic. The salt is very volatile; even at room temp., T. Curtius and R. Radenhausen said that the crystals volatilize slowly, and in a few days disappear; and the last traces of the salt, with mineral acids, yield hydrazoic acid. The salt fuses at 160°, and at the same temp., it begins to boil and sublime. T. Curtius said that when warmed in a test-tube, sublimation begins at about 100°; if rapidly heated, the salt explodes. Vapour density determinations at 100° gave half the value calculated for N_4H_4, and this corresponded with a complete dissociation of the salt. D. I. Mendeléeff suggested that ammonium azide like ammonium cyanate should undergo an isomeric change when heated, but T. Curtius and R. Radenhausen obtained no evidence of this. M. Berthelot and P. Vieille gave 1350°–1500° for the temp. of the explosion, and they represented the reaction: $2N_4H_4=3N_2+H_2+2NH_3$, and 11–20 per cent. of the ammonia is decomposed. A. R. Hitch found that when heated the salt has a tendency to sublime, and it decomposes into ammonia, nitrogen, and hydrogen. M. Berthelot and C. Matignon gave for the heat of formation: $(4N,4H)=N_4H_4-25{\cdot}3$ Cals., with the solid salt, and $-32{\cdot}3$ Cals. if in soln. R. Bach gave for the heat of neutralization $(NH_3aq.,HN_3aq.)=NH_4.N_3aq.+83$ Cals.; and M. Berthelot and C. Matignon, 8·2 Cals. The heat of soln. is $-7{\cdot}08$ Cals., and R. Bach gave $NH_3.N_3H+Aq.=NH_3.HN_3.Aq.+67{\cdot}34$ Cals. M. Berthelot and C. Matignon found for the heat of combustion, $N_4H_{4\text{cryst.}}+O_2=2N_2+2H_2O+163{\cdot}8$ Cals. at constant vol., and $+163{\cdot}3$ Cals. at constant press. T. Curtius and J. Rissom studied the spectrum of ammonium azide. W. Hittorf found that on electrolysis of the aq. soln., nitrogen was evolved from a platinum anode, and hydrogen and free ammonia from the cathode. A. W. Browne and co-workers found that when a soln. of a gram of ammonium azide in 36 c.c. of liquid ammonia is electrolyzed, copper anodes undergo electrolytic corrosion to an extent indicating the formation of some cuprous azide, CuN_3, with cupric azide, CuN_6, as the main product. No gas was liberated at the anode. With silver, cadmium, lead, and antimony anodes the corrosion resulted in the formation of normal azides, AgN_3, CdN_6, PbN_6, and SbN_9, without liberation of gas at the anode. Aluminium, iron, and nickel anodes undergo corrosion, accompanied by the liberation of nitrogen. The aluminium anode became coated with a bulky pyrophoric scale of varying colour and texture. Deep red ferric azide, FeN_9, was obtained in soln. when an iron anode was employed, but this product was ammonolyzed and yielded an ammono-basic ferric azide. A pink deposit was formed on the nickel anode, presumably an ammono-basic nickel azide. F. Friedrichs, and A. W. Browne and A. E. Houlehan found ammonium azide to be readily soluble in liquid ammonia, and at 110°, the soln. gives two liquid phases; and F. A. Smith measured the conductivity of the soln. F. Friedrichs also found that the azide dissolves in liquid sulphur dioxide, forming two soln. of limited miscibility.

T. Curtius and J. Rissom made **lithium azide,** LiN_3, by the action of a soln. of lithium sulphate on barium azide, and evaporating the clear liquid. The anisotropic crystals were hygroscopic and could not be recrystallized from aq. soln. The salt dissolves in water without the development of heat; the soln. has an alkaline reaction. 100 parts of water at 10° dissolve 36·12 parts of salt; at 15·5°, 62·07 parts; and at 16°, 66·41 parts; again, 100 parts of alcohol dissolve at 16°, 20·26 parts of salt. Lithium azide is insoluble in ether. When the dry or moist salt is heated, decomposition occurs with explosive violence; the decomposition temp. ranges from 115° to 298° according to the rate of heating. L. Wöhler and F. Martin gave 245° for the temp. of detonation of lithium azide. The salt does not explode by percussion. L. M. Dennis and A. W. Browne added that the salt never crystallizes free from water; but always contains a mol of water. L. M. Dennis and C. H. Benedict evaporated a soln. of lithium hydroxide neutralized with hydrazoic acid, in air, and obtained colourless, hygroscopic crystals of **hydrated lithium azide,** $LiN_3.H_2O$, which were readily soluble in water, and soluble in alcohol. L. M. Dennis and C. H. Benedict made **sodium azide,** NaN_3, by evaporating a soln. of sodium hydroxide neutralized with hydrazoic acid; T. Curtius saponified benzoylazide with an alcoholic or aq. soln. of sodium hydroxide; and W. Wislicenus passed a mixture of ammonia and nitrous oxide over molten sodium, or treated sodium amide at 150°–250° with nitrous oxide. According to W. Schlenk and T. Weichselfelder, when thin slices of sodium are gradually added to ordinary free hydrazine in an atm. of pure, dry nitrogen, a colourless precipitate is formed and the liquid develops a yellow colour. The deposit is sodium hydroxide, for the best hydrazine still contains some hydrate. By treating hydrazine in this way until the yellow colour was permanent, and then distilling the hydrazine in a vacuum, the authors have obtained absolute hydrazine, which then dissolved sodium completely with the evolution of ammonia and a little hydrogen. On evaporating the yellow soln., **sodium hydrazide,** $NH_2.NHNa$, remained as a residue of glistening leaflets. It was found to be most violently explosive. A mere breath of air, or a trace of moisture or alcohol, sufficed to produce disastrous results. The preparation of sodium azide was described by B. P. Orelkin and co-workers, and J. Thiele by heating hydrazine hydrate with an aq. soln. of sodium nitrite. According to A. W. Browne and F. Wilcoxon, sodium nitrate is ammonolyzed in contact with fused sodium amide as indicated above. The clear, colourless crystals were found by H. Rosenbusch to be uniaxial hexagonal plates with a strong positive birefringence. According to S. B. Hendrichs and L. Pauling, the X-radiogram of sodium azide agrees with a rhombohedral structural unit containing one NaN_3-mol., and having $\alpha=38°\ 43'$, and $a=5{\cdot}418$ A. L. M. Dennis and C. H. Benedict said the crystals are not hygroscopic; they are not explosive when struck with a hammer; and can be melted without decomposition, but, added T. Curtius and J. Rissom, they detonate at a higher temp. The salt is not decomposed when kept 30 mins. at 350°. E. Tiede gave 330° for the temp. at which sodium azide begins to decompose, in vacuo, and he found that nitrogen came off regularly at 380°. E. Moles gave respectively 300° and 280°. Sodium is deposited on the sides of the reaction vessel. The reaction was also studied by A. R. Hitch. J. A. Cranston and A. Y. Livingstone found the sp. gr. of sodium azide to be 1·846 at 20°; and for the sp. gr. and refractive index of the aq. soln., at 16°,

NaN_3 solution	*N*-	0·5*N*-	0·25*N*-	0·125*N*-
Sp. gr.	0·979	0·954	0·946	0·941
Refractive index	1·371	1·362	1·359	1·351

C. A. West gave for the mol. conductivity of soln. of sodium azide:

v	32	64	128	256	512	1024	2048
μ	100·8	102·9	104·8	105·5	107·2	107·9	107·8

so that $\mu_\infty=10\cdot9$. The rate of increase in the conductivity with rise of temp. is about 2·7 per cent. per degree. J. W. Turrentine studied the electrolysis of 2 per cent. soln. of sodium azide with anodes of various metals. The electrochemical eq. of magnesium is twice as great as would be expected from Faraday's law. Aluminium, zinc, and cadmium also give anode efficiencies of considerably more than 100 per cent. In order to explain these phenomena, it is suggested that the metals dissolve electrochemically at a valency lower than that usually assigned to them with formation of compounds which are readily oxidized. This hypothesis is supported by the fact that reduction products of the N'_3 ion, such as ammonia, hydrazine, and nitrogen, are found in the region of the anode, the presence of which indicates that some reducing agent is formed at the anode. The evolution of nitrogen at the anode was taken to mean that the azide ion was being reduced by magnesium, aluminium, or zinc azides. E. Briner and P. Winkler found that when an alkaline soln. of hydrazoic acid is electrolyzed, nitrogen is liberated at the anode, but the quantity is not the theoretical. A. Peratoner and G. Oddo attribute the deficiency to formation of nitric acid. If the formation of nitric oxide could be proved by the interaction of anodic nitrogen and nascent oxygen, this would furnish an argument in favour of the atomic fixation of nitrogen, the atomic nitrogen coming from the decomposition of the N_3-ion. The formation of nitric acid by the electrolysis of an alkaline soln. of an azide has been confirmed. Such a soln. evolves much free oxygen with the nitrogen, but the amount of nitric acid formed is very small. When a neutral azide soln. was electrolyzed and a stream of oxygen was led into the anodic nitrogen, no nitric oxide was found in the gases, and the amount of nitric acid in soln. was even less than from the alkaline soln. When ozone was used with the oxygen, the nitric acid reaction in the soln. became very distinct. When hydrogen was led into the anode chamber very minute quantities of ammonia were formed, but when an aluminium anode was used, causing the formation of nascent hydrogen by soln. of the metal in the alkaline liquid, ammonia was formed. Only one-third of the nitrogen of the azide is converted into ammonia, the other two-thirds escaping as nitrogen. It may be taken, therefore, that the azoic group decomposes according to the equation $N_3=N_2+N$, giving rise to an atom of nascent hydrogen. J. A. Cranston and A. Y. Livingstone found that the eq. electrical conductivity in methyl alcohol of sp. gr. 0·789 at 20°, is at 25°:

NaN_3 . .	0·1*N*-	0·05*N*-	0·025*N*-	0·0125*N*-
Eq. conductivity .	58·7	69·0	78·8	90·4

T. Curtius observed that sodium azide is insoluble in ether. 100 parts of alcohol at 16° dissolve 0·3153 part of salt; and J. A. Cranston and A. Y. Livingstone found that the solubility of sodium azide in 100 c.c. of solvent, with alcohol of sp. gr. 0·799 at 17°, is 0·22 at 0°, and 0·46 at the b.p. of the soln.; and in benzene at the b.p., it is 0·10. T. Curtius gave for the solubility in 100 parts of water, at 10°, 40·16 parts of salt; at 15·2°, 40·7 parts; and at 17°, 41·7 parts. The dissolution of the salt is attended by a fall of temp., and the soln. has an alkaline reaction. J. A. Cranston and A. Y. Livingstone found the sp. gr. at 20° is 2·056; and for the sp. gr. and refractive index of the aq. soln., at 16°:

KN_3 solution .	0·5*N*-	0·25*N*-	0·125*N*-	0·0625*N*-
Sp. gr. . .	0·956	0·948	0·941	0·938
Refractive index .	1·362	1·360	1·359	1·357

The eq. electrical conductivity in methyl alcohol of sp. gr. 0·789 at 20°, is, at 25°:

KN_3 . . .	0·1*N*-	0·05*N*-	0·025*N*-	0·0125*N*-
Eq. conductivity .	58·7	69·0	78·8	90·4

It will be noted that the solubility of azides of the alkali metals increases as the at. wt. of the alkali metal increases; and that their solubility in alcohol decreases with increasing at. wt. of the alkali metal. J. A. Cranston and A. Y. Livingstone showed that in the presence of platinum black, the alkali azide is decomposed;

$3KN_3+3H_2O=3KOH+4N_2+NH_3$. K. A. and U. Hofmann found that sodium azide reacts with molecular hydrogen and oxygen, forming in the one case $NaNH_2$ with the evolution of nitrogen, and in the other case $NaNO_2$. F. Friedrichs found that sodium azide is readily soluble in liquid ammonia and shows a critical soln. of temp. It is insoluble in liquid sulphur dioxide. According to D. A. Spencer, bromine water reacts instantly with sodium azide soln. to give a mixture of hydrazoic and hypobromous acids, which then interact to produce nitrogen. When the sodium azide is present in quantities larger than are required by the equation: $NaN_3+Br_2+H_2O=NaBr+HN_3+HBrO$, the nitrogen evolution is more rapid owing to the interaction of the hypobromous acid with the excess of sodium azide, and it is for this reason that two equivalents of bromine are able to decompose two equivalents of sodium azide. W. Strecker and L. Claus found that sodium azide reacts with selenium monobromide in the presence of benzene, forming sodium bromide and selenium; and with selenyl chloride, forming nitrogen and $2NaCl.SeO_2.H_2O$. A conc. soln. was found by H. Stamm to give a precipitate with ammonia.

L. M. Dennis and C. H. Benedict made **potassium azide,** KN_3, by evaporating a soln. of potassium hydroxide neutralized with hydrazoic acid. Crystals are readily formed. A slight excess of the acid is desirable. The uniaxial crystals are tetragonal, with the axial ratio $a:c=1:0·57976$. T. Curtius and J. Rissom gave 1 : 0·5810. The optical character is negative, and the crystals are strongly double refracting. S. B. Hendrichs and L. Pauling examined the X-radiogram, and found that the structural unit resembled that of potassium cyanate, being tetragonal with $a=6·094$ A., and $c=7·056$ A., and having four KN_3-mols. per unit cell. According to T. Curtius and J. Rissom, the salt is neither volatile nor hygroscopic. It does not explode when struck with a hammer. When heated, the salt melts and boils; nitrogen is then given off, and the residue inflames with a feeble detonation. It is not changed when heated to 350° in a capillary tube, and at a higher temp., nitrogen is evolved and potassium is formed. E. Tiede found that potassium azide begins to decompose in vacuo at 320°, and nitrogen comes off regularly at 360°. The reaction was also studied by A. R. Hitch—*vide supra*, sodium azide. A. W. Browne and A. B. Hoel used filter-paper impregnated with potassium azide as fuse-paper to detonate silver azide. T. Curtius found that the salt dissolves in water with the production of cold, 100 parts of water at 10·5° dissolve 46·5 parts of salt; at 15·5°, 48·9; and at 17°, 49·6. Again, 100 parts of alcohol dissolve 0·1375 part of salt at 16°; and J. A. Cranston and A. Y. Livingstone found that the solubilities of potassium azide in 100 c.c. of alcohol of sp. gr. 0·799 at 17° are 0·16 at 0°, and 0·54 at the b.p.; with 80 per cent. alcohol at 0°, 1·8, and at the b.p., 5·9; and in benzene at the b.p., it is 0·15. T. Curtius found that the salt is insoluble in ether. The aq. soln. has an alkaline reaction—*vide supra* for the effect of platinum black. According to F. Friedrichs, potassium azide is soluble in liquid ammonia, and shows a critical soln. temp. The salt is only slightly soluble in liquid sulphur dioxide, and at 120°, the salt becomes yellow, and then explodes. According to A. W. Browne and A. B. Hoel, when manganese dioxide is gently heated with potassium azide, the reaction is very violent, and the product leached with water furnishes a green soln. of manganate which soon becomes violet permanganate. J. A. Cranston and A. Y. Livingstone compared the properties of the alkali azides and cyanates and found them to be so much alike that they supposed that the arrangement of the electrons and atoms in the cyanate-ions and azide-ions is the same, and in accord with I. Langmuir's octet theory—**4.** 27, 4—and not respectively:

$$Na{-}N{<}\genfrac{}{}{0pt}{}{N}{N} \qquad\qquad Na{-}O{-}C{\equiv}N$$

T. Curtius and J. Rissom, and L. M. Dennis and C. H. Benedict made the **rubidium azide,** RbN_3, by the methods indicated in connection with lithium azide.

The salt readily crystallizes furnishing plates with the axial ratio $a : c = 1 : 0·5785$. The salt is hygroscopic, and is not decomposed when the aq. soln. is evaporated. The salt is not exploded when struck with a hammer. When heated in a capillary tube, it sinters at 230°, and melts at 330°–340°, and at a higher temp., it leaves a metallic mirror of rubidium, and nitrogen is evolved. E. Tiede found that rubidium azide begins to decompose, in vacuo, at 260°, and nitrogen comes off regularly at 310°. The salt is insoluble in ether; 100 parts of water, at 6°, dissolve 107·1 parts of salt; and at 17°, 114·1 parts; likewise 100 parts of alcohol dissolve 0·182 part of salt at 16°. The aq. soln. reacts alkaline. The aq. soln. has an alkaline reaction. In a similar manner was **cæsium azide,** CsN_3, prepared in small, hygroscopic, uniaxial crystals with a strong, negative, double refraction. The salt does not explode by percussion, and it behaves like potassium azide on a hot plate. It melts in a capillary tube at 310°–318°, and behaves like the rubidium salt at a higher temp. E. Tiede found that cæsium azide begins to decompose, in vacuo, at 290°, and nitrogen comes off regularly at 300°. The salt is insoluble in ether; 100 parts of water at 0° dissolve 224·2 parts of salt; and at 16°, 307·4 parts; while 100 parts of alcohol, at 16°, dissolve 1·0366 parts of salt. The aq. soln. has an alkaline reaction.

L. Wöhler and W. Krupko prepared **cuprous azide,** CuN_3, by gradually adding a soln. of sodium azide to an excess of a conc. soln. of copper sulphite to which potassium sulphite has been previously added followed by acetic acid in quantity just sufficient to dissolve the precipitate formed. The pale greenish-grey cuprous azide inflames at 220°. When exposed to light, it becomes deep red with a violet tinge and furnishes copper and nitrogen. A. W. Browne and co-workers found that cuprous azide is formed by the electrolysis of a soln. of ammonium azide in liquid ammonia, at —67°, using copper anodes. T. Curtius and J. Rissom prepared **cupric azide,** CuN_6—possibly with $\frac{1}{2}H_2O$, or H_2O—by mixing dil. aq. soln. of copper sulphate and sodium azide; washing the precipitate with ice-water, and drying in a desiccator. It was also obtained by the action of 3·87 per cent. hydrazoic acid on copper precipitated by zinc. The product is cupric, not cuprous azide. A. W. Browne and co-workers found that cupric azide is formed by the electrolysis of a soln. of ammonium azide in liquid ammonia, at —67°, using copper anodes. Copper azide is very explosive even when moist, so that it has not been tried for analysis; it is therefore not clear if the salt is anhydrous, hemihydrated, or monohydrated. The brown product consists of anisotropic prisms which are yellow in transmitted light. It is slightly soluble in water, forming a green soln., and boiling water decomposes it slowly with the formation of hydrazoic acid, and copper hydroxide. Cupric azide explodes by friction, even loosening the solid from the filter-paper suffices for the detonation; the explosion by percussion is very violent. A. R. Hitch could not decompose it thermally without explosion. L. Wöhler and F. Martin gave 174° for the temp. of explosion. According to L. Wöhler and W. Krupko, *basic cupric azide,* **cupric oxyazide,** $CuO.CuN_6$, is formed as a yellow hydrated substance when water with normal cupric azide in suspension is heated to 70°–80° in a current of air freed from carbon dioxide until the calculated quantity of hydrazoic acid has been evolved. It inflames at 245°. L. M. Dennis and H. Isham obtained **cupric amminoazide,** $Cu(NH_3)N_3$, by shaking freshly precipitated black cupric hydroxide, while still moist, with an cxcess of hydrazoic acid; and washed the precipitate. A soln. of the precipitate in aq. ammonia deposits crystals of the salt. It explodes when heated or struck. It is insoluble in water, and soluble in dil. acids.

T. Curtius showed that when a dil. soln. of hydrazoic acid is added to silver nitrate soln., **silver azide,** AgN_3, is precipitated quantitatively; indeed, silver nitrate gives a perceptible turbidity with soln. containing one part of acid in a million parts of soln. J. Thiele made the salt by the addition of an ammoniacal soln. of a silver salt to a soln. of diazoguanidine nitrate; the filtrate from the yellow CN_5Ag_3 when treated with dil. nitric acid gave a little silver azide. A. Angeli found that when a cold sat. soln. of silver nitrate is added to a soln. of hydrazine, white needles of silver azide are deposited. A. W. Browne observed that silver azide is formed when a soln. of ammonium azide in liquid ammonia, at —67°, is electrolyzed with a silver anode. T. Curtius showed that when the ammoniacal soln. of silver azide is evaporated, colourless needle-like crystals of the azide are formed; the anisotropic prisms melt at 250°. A. R. Hitch gave 253°–254° for the m.p.; and the azide explodes at about 300° in agreement with L. Wöhler's observation. Nitrogen is given off very slowly at about 251°, and there is a slight ebullition at 253·5°. The salt is very liable to explode, and the detonation produced when a few milligrams is heated or struck, is very violent. L. Wöhler and F. Martin gave 297° for the temp. of detonation. C. A. Taylor and W. H. Rinkenbach studied this subject. A. W. Browne and A. B. Hoel detonated silver azide with fuse-paper impregnated with potassium azide—*vide supra.* The salt is stable in air; but is very sensitive to light, and when insolated, readily decomposes into nitrogen and the metal. L. Wöhler and W. Krupko said that a specimen which had been exposed to light for such a period that decomposition had not occurred beyond the stage corresponding with the possible formation of a subazide, particles of metallic silver were visible under the microscope, and the residue behaved like silver azide when heated or subjected to percussion. L. M. Dennis said that 100 c.c. of boiling water dissolve about 0·01 grm. of silver azide which separates from the cooling soln. in needle-like crystals. T. Curtius said that the salt is virtually insoluble in water and in dil. acids; but unlike silver chloride, added L. M. Dennis, it is fairly soluble in hot dil. nitric acid (1 : 4). D. A. Spencer found that silver azide reacts instantly with bromine water: $2AgN_3+Br_2=2AgBr+3N_2$. The only evidence of the momentary formation of bromazide in aq. soln. is the production of a little hydrazoic acid with the loss of free nitrogen. According to F. Friedrichs, silver azide dissolves in liquid ammonia and the two liquid phases have a critical soln. temp. At about 100°, the mixture becomes explosive. The salt is scarcely soluble in liquid sulphur dioxide, and by raising the temp., the mixture is very explosive. L. M. Dennis and A. W. Browne found silver azide to be decomposed by boiling with dil. sulphuric acid; to be soluble in conc. mineral acids; and to be soluble in aq. ammonia—the ammoniacal soln. can be boiled without reduction. W. Strecker and L. Claus found that silver azide reacts with selenium monobromide suspended in benzene, forming silver bromide and selenium; while selenium tetrabromide forms a pale yellow compound which becomes bluish-black when exposed to light. J. Bekk found that the photographic behaviour of silver azide resembles that of silver chloride and bromide, but its sensitiveness to light is much less than that of the halogen salts. The azide is also much more easily reduced by developing soln., and, in the unripened condition, is characterized by relatively high sensitiveness to the red portion of the spectrum. The first two properties are, in all probability, determined to a large extent by the extreme fineness of the granular structure of the azide. The darkening of silver azide has been shown to be accompanied by the liberation of nitrogen. Although the pure substance is highly explosive, it is found that dried emulsions of silver azide are quite insensitive to shock, and can be manipulated without danger. T. Curtius and J. Rissom added sodium or potassium azide to a soln. of auric chloride, and on evaporating the liquid, obtained needle-like crystals of a **gold azide.** Both the aq. soln. and the dry salt are very liable to explode.

The azides of the alkaline earths were made by T. Curtius and J. Rissom by dissolving the oxides or hydroxides in dil. hydrazoic acid—say 2–8 per cent. The excess of alkaline earth can be removed by passing carbon dioxide into the boiling soln., and the filtrate conc. by evaporation. There remain colourless, rhombic needles of **calcium azide,** CaN_6; and, according to L. M. Dennis and C. H. Benedict, spherical masses of minute crystals may be formed. The crystals are very hygroscopic and deliquescent. T. Curtius found that the salt does not explode by percussion, but it does so if rapidly heated on a metal plate, and it explodes at about 144°–156°

when heated in a capillary tube; when the temp. has attained 120°–130°, metallic calcium appears in the capillary. E. Tiede found that calcium azide begins to decompose, in vacuo, at 100°, and nitrogen comes off regularly at 110°. L. Wöhler and F. Martin gave 158° for the temp. of explosion. T. Curtius and J. Rissom showed that 100 parts of water dissolve 38·1 parts of salt at 0°, and 45·0 parts at 15·2°. The dissolution of the salt results in the cooling of the soln.; the salt is not changed by the evaporation of the aq. soln. 100 parts of alcohol dissolve 0·211 part of salt at 16°. It is insoluble in ether. T. Curtius and J. Rissom prepared **strontium azide,** SrN_6, in a similar way. It is not explosive by percussion and behaves on a hot plate like calcium azide. The glittering plates are hygroscopic. In a capillary tube, it explodes at 194°–195°, and forms metallic strontium at 140°–150°; L. Wöhler and F. Martin gave 169° for the temp. of explosion. E. Tiede found that strontium azide begins to decompose, in vacuo, at 100°, and to give off nitrogen regularly at 140°. A. Petrikaln studied the explosion spectra of the azides of the alkaline earths. T. Curtius and J. Rissom found that 100 parts of water dissolve 45·83 parts of salt, at 16°, and the aq. soln. has an alkaline reaction, but the salt is not changed by evaporation. 100 parts of alcohol dissolve 0·095 part of the salt at 16°; and the salt is insoluble in ether. The salt was also made by L. M. Dennis and C. H. Benedict. M. Berthelot and C. Matignon, and T. Curtius and J. Rissom made **barium azide,** BaN_6, in fine needles or rhombic prisms which, according to H. Rosenbusch, have the axial ratios $a:b:c=0·3424:1:0·8461$. L. M. Dennis and co-workers say that when evaporated over sulphuric acid, crystals of **monohydrated barium azide,** $BaN_6.H_2O$, are formed. T. Curtius and J. Rissom said that barium azide is hygroscopic, and it does not explode by percussion, and behaves on a hot plate like the calcium salt. In a capillary tube, it explodes at 217°–221°, and at about 180°, metallic barium is present. E. Tiede found that, in vacuo, barium azide begins to decompose at 120°, and gives off nitrogen regularly at 160°. A. R. Hitch found that barium azide suffered no change until about 180° was reached when nitrogen was evolved. At 225°, the salt exploded. L. Wöhler and F. Martin gave 152° for the temp. of explosion. According to E. Ebler, barium azide is not decomposed by radium rays. M. Berthelot found the heat of soln. to be 7·8 Cals. T. Curtius and J. Rissom said that 100 parts of water dissolve 12·5 parts of salt at 0°; 16·2 parts at 10·5°; 16·7 parts at 15°; and 17·3 parts at 17°. The solubility of alkaline earth azides in water increases as the at. wt. of the metal increases. 100 parts of alcohol dissolve 0·0172 part of barium azide at 16°. The salt is virtually insoluble in ether. E. Ebler prepared **radium azide**—probably RaN_3—by dissolving the carbonate in aq. hydrazoic acid. The salt was slowly heated in a capillary to 180°–250°, and a shining metallic mirror of elemental radium was formed.

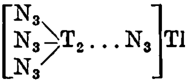
T. Curtius and J. Rissom found that only an impure **beryllium azide** is obtained from a beryllium salt and an azide; they prepared **magnesium azide,** MgN_6, by dissolving magnesium in hydrazoic acid; and by the action of a soln. of magnesium sulphate on barium nitride. The salt explodes when heated. The salt readily dissolves in water; and by boiling with water, the salt loses its explosive qualities. For *magnesious azide, vide supra,* sodium azide. T. Curtius and co-workers dissolved zinc in hydrazoic acid, and observed the evolution of hydrogen with some ammonia, and the formation of anisotropic crystals of a *basic zinc azide,* **zinc hydroxyazide,** possibly $Zn(OH)N_3$. The salt is sparingly soluble in water. W. Wislicenus obtained **zinc azide,** ZnN_6, by the action of nitrous oxide on zinc amide, $Zn(NH_2)_2$, at 150°–250°. L. M. Dennis and H. Isham obtained a soln. of zinc azide in methyl alcohol by the electrolysis of a 6 per cent. soln. of hydrazoic acid in methyl alcohol, using zinc as anode, and platinum as cathode; and, more slowly, by the action of the soln. on zinc in excess. A. Petrikaln studied the explosion spectrum of zinc azide. For *zincous azide, vide supra,* sodium azide. If dry ammonia be passed through the soln. of zinc azide, a white precipitate of **zinc diamminoazide,** $Zn(NH_3)_2N_6$, is produced. Some crystals of the less soluble ammonium azide may be formed. The salt appears in white, acicular crystals, which may be heated without explosion; L. Wöhler and F. Martin gave 289° for the temp. of explosion. The salt is insoluble in water, but in contact with that liquid, the salt becomes opaque, presumably owing to the hydrolytic formation of zinc hydroxide. T. Curtius and J. Rissom obtained **cadmium azide,** CdN_6, by evaporating in a desiccator a soln. of cadmium carbonate in an excess of hydrazoic acid. The salt furnishes tabular crystals which do not explode by percussion. A. W. Browne and co-workers found that cadmium azide is formed when a soln. of ammonium azide in liquid ammonia, at −67°, is electrolyzed with cadmium anodes. L. Wöhler and F. Martin gave 291° for the temp. of explosion. If pyridine be added to an aq. soln. of cadmium azide, a complex *cadmium pyridine azide,* $Cd(C_5H_5N)_2N_6$, is formed.

T. Curtius prepared **mercurous azide,** HgN_3, by treating a soln. of the acid with mercurous nitrate, and M. Berthelot and P. Vieille, by adding a dil. aq. soln. of ammonium azide to mercurous nitrate, and washing the product, first by decantation, and lastly on the filter. The white powder resembles mercurous chloride, and, according to T. Curtius, consists of microscopic, anisotropic needles. It is more sensitive to light than silver azide. When exposed to light, it turns yellow without suffering any other visible change. L. Wöhler said that the yellow colour is produced by the formation of the colloidal metal and nitrogen; the yellow colour passes to orange, brown, black, and finally grey. L. Wöhler and W. Krupko said that unlike mercurous chloride or other mercurous salt, no mercuric azide is formed. T. Curtius said that the azide is less sensitive than lead azide to percussion. According to L. Wöhler, the salt is less explosive than silver azide; and F. Martin made a study of its sensitiveness to explosion. It explodes after some time if kept in darkness and in vacuo at 140°; L. Wöhler and W. Krupko gave 245° as the temp. of detonation; F. Martin, 281°; and L. Wöhler, and F. Martin, 281°. A. R. Hitch found that mercurous azide remains white up to 220°, beyond which it turns yellow, darkens in colour, becoming almost black. It begins to sublime at about 220°; an evolution of gas begins at about 215°, and assumes explosive violence at 270°. F. Martin gave 50·897 Cals. for the heat of detonation. M. Berthelot and P. Vieille gave ±144·6 Cals. for the heat of decomposition. L. Wöhler and W. Krupko said that on percussion the salt immediately decomposes into mercury and nitrogen, and the non-formation of *mercury subazide,* Hg_2N_3, is confirmed by the absence of hydrazoic acid from the products of decomposition of mercurous azide suspended in water. In darkness, the salt may be kept under water for some months without change; the dry salt in vacuo, in darkness, does not change in 24 hrs. at 120°–140°; in gaslight for 24 hrs., the salt becomes pale yellow; and in sunlight it instantly becomes yellow, then dark brown, and black, and finally grey. They found that 100 c.c. of water at ordinary temp. dissolve 0·025 grm. of the salt. T. Curtius said that when treated with dil. aq. ammonia, mercurous azide forms a black insoluble compound. M. Berthelot and P. Vieille obtained **mercuric azide,** HgN_6, by saturating hydrazoic acid with freshly precipitated mercuric oxide. A. Stellbacher prepared mercuric azide as follows:

> A soln. of 6·5 grms. of sodium azide was decomposed with conc. sulphuric acid, and the gaseous hydrogen nitride produced was passed into 10 grms. of mercuric oxide in 200 c.c. of boiling water. The hot soln. of mercuric azide was passed through a filter in a funnel provided with a hot-water jacket, and the filtrate was gently agitated with a wooden splinter during cooling to avoid formation of crystals exceeding 1 mm. in length, these being extremely sensitive. A crystalline mass of mercuric azide was thus obtained of not appreciably greater sensitiveness than silver fulminate. An alternative method consists in mixing conc. soln. of sodium azide and mercuric nitrate; mercuric azide is precipitated from this mixture as a powdery mass, which is even less sensitive than lead azide, but can be converted into the highly sensitive form by solution and crystallization.

The white powder is soluble in hot water; but very sparingly soluble in cold water. On cooling the hot soln., the salt separates in long, white, acicular crystals. The salt is said to be very explosive. A. R. Hitch said that when mercuric azide was heated, gas came off at 212°, and the salt began to boil at 215°; and it exploded at 300°. A. Stettbacher concluded that the extreme sensitiveness of mercuric azide, even under water, renders it unsuitable as a detonating agent. It has the same mol. wt. as mercuric fulminate, and develops the same vol. of gas on detonation, but its *brisance* is twenty times as great. L. Wöhler gave 200°–210° for the temp. of explosion. The salt rapidly becomes yellowish-brown when exposed to sunlight or to ultra-violet rays. L. Wöhler and F. Martin, and C. A. Taylor and W. H. Rinkenbach, studied the influence of the size of grain on the sensitiveness to explosion. L. Wöhler said that no basic mercuric azide is produced when a soln. of hydrazoic acid is warmed with an excess of mercuric oxide, while mercuric azide is not changed when air is passed through water with the salt in suspension.

According to L. M. Dennis, when a soln. of ammonia-alum is treated with an alkali azide, aluminium hydroxide is precipitated, and not *aluminium azide.* For *aluminous azide, vide supra,* sodium azide. T. Curtius and J. Rissom, and L. M. Dennis and co-workers, showed that **thallous azide,** TlN_3, is formed as a white precipitate when ammonium or potassium azide, or hydrazoic acid is added to a soln. of thallous sulphate or nitrate. Thallous azide furnishes transparent, pale yellow tetragonal crystals, which are not hygroscopic. When exposed to light, a thin brown crust forms on the surface—presumably owing to the formation of thallous oxide. The salt is not explosive when heated under ordinary conditions, but when struck with a hammer an explosion occurs. When heated on a hot plate, the salt melts, and boils. Thallium is produced when the salt is heated in a capillary tube. The azide is not altered at 340°, but explodes at a higher temp. L. Wöhler and F. Martin gave 320° for the temp. of explosion. The salt melts at 334°, in an atm. of carbon dioxide, and it is not volatile when heated in nitrogen or hydrogen, the salt is reduced, and in some cases approximately one-third the nitrogen present is converted into ammonia: $N_3H+H_2 \rightarrow N_2+NH_3$. A. R. Hitch said that the salt suffered no change below 330°; at that temp. it melted to a colourless liquid, and it began to sublime at 340°. Nitrogen was evolved at 370°, and an explosion occurred at 430°. Thallous azide is sparingly soluble in cold water, and readily soluble in hot water; 100 c.c. of water at 0° dissolve 0·1712 grm. of the salt; at 5°, 0·1965 grm.; and at 16°, 0·3 grm. The salt in neutral aq. soln. is not altered by evaporation. T. Curtius and J. Rissom added that the spectrum from thallous nitride resembles that from thallous chloride. L. M. Dennis and co-workers found that yellow, needle-like crystals of **thallosothallic azide,** $TlN_3.TlN_9$, are formed when a soln. of freshly precipitated thallic hydroxide in hydrazoic acid is cooled by a freezing mixture. The composition on the co-ordination theory is represented



$$\left[\begin{array}{l}N_3\searrow\\N_3\rightarrow T_2\ldots N_3\\N_3\nearrow\end{array}\right]Tl$$

If the soln. be allowed to crystallize at ordinary temp., *thallic azide,* if it is formed at all, is decomposed with the escape of hydrazoic acid, and the precipitation of thallic hydroxide. Warm water likewise decomposes thallosothallic azide into thallic and thallous hydroxides.

T. Curtius and A. Darapsky prepared a basic salt, **lanthanum hydroxyazide,** $La(OH)(N_3)_2 1\frac{1}{2}H_2O$, by boiling a soln. of lanthanum nitrate and sodium azide. The white, slimy mass of basic lanthanum azide is obtained by evaporating the mixed soln. in vacuo, or by treatment of the soln. with a mixture of alcohol and ether. They also made rose-coloured **didymium hydroxyazide,** $Dy(OH)(N_3)_2$, by evaporating a soln. of didymium carbonate in hydrazoic acid. Freshly precipitated yttrium hydroxide dissolves in hydrazoic acid, forming a soluble *yttrium hydroxyazide;* boiling a soln. of yttrium sulphate and sodium azide gives a precipitate of yttrium hydroxide. L. M. Dennis found that *zirconium hydroxide* is precipitated when a soln. of zirconium salt is treated with potassium azide.

According to T. Curtius and J. Rissom, **tin azide** has been prepared only in a very impure state. A 17 per cent. soln. of hydrazoic acid attacks tin-foil with the evolution of gas and the separation of a white compound which is insoluble in water, and is not explosive. An aq. soln. of stannous chloride gives with sodium azide a precipitate which is thought to be a mixture of stannous azide and hydroxide. It gives off hydrazoic acid when heated with sulphuric acid.

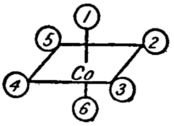
T. Curtius and J. Rissom prepared **lead azide,** PbN_6, by precipitation from a lead salt soln. by hydrazoic acid, or a soln. of ammonium or sodium azide. J. W. Turrentine found a dark brown deposit formed on the lead anodes during the electrolysis of a 30 per cent. soln. of sodium azide; he said that this deposit is probably lead azide, or some other nitride. W. R. Hodgkinson made lead azide by treating hydrazine nitrate with sodium nitrate until the soln. no longer reddens litmus, and then adding lead nitrate soln.; and A. G. Lowndes, by adding lead acetate to a soln. of sodium azide in the presence of sodium nitrate. A. W. Browne and coworkers found that lead azide, PbN_6, is formed when a soln. of ammonium azide in liquid ammonia, at −67°, is electrolyzed with a lead anode. The hot aq. soln., on cooling, furnishes colourless, needle-like crystals which T. Curtius said have only a formal resemblance to those of silver chloride. According to A. G. Lowndes, large crystals are avoided when 0·5 per cent. of dextrine or gelatine is present in soln., and the crystals are smaller if the conc. or the viscosity of the soln. is raised by a non-colloidal addition. Lead azide is very explosive, and it decomposes when warmed. A. R. Hitch said that the salt can be decomposed at 245°–250° without explosion, but it is very liable to explode. The salt decomposes before it melts. L. Wöhler gave 350° for the temp. of explosion; L. Wöhler and F. Martin gave 327°. The explosive properties were also discussed by A. Stettbacher, H. Goldschmidt, F. Martin, W. G. Hudson, C. A. Taylor and W. H. Rinkenbach, and L. Wöhler and W. Krupko. Lead azide can be used in place of mercury fulminate as a detonator for high explosives. L. Wöhler and W. Krupko said that the salt is not changed if kept dry in darkness for 24 hrs. at 115°; but there is a small loss in weight at 170°. Lead azide is extremely sensitive to light; and when exposed to sunlight, it is immediately covered with a dark brown film. From the temp. and percussion tests, it is inferred that the dry salt decomposes into lead and nitrogen when exposed to light. When exposed to air or placed under water, oxidation of the separated lead proceeds simultaneously, and the product consists of lead azide mixed with finely-divided lead hydroxide. The filtrate contains traces of lead, hydrazoic acid, and considerable quantities of ammonia. Reaction thus appears to proceed simultaneously according to the three equations: (i) $PbN_6+2H_2O=Pb(OH)_2+2N_3H$; (ii) PbN_6(in light) $=Pb+3N_2$; (iii) $Pb+N_3H+2H_2O=Pb(OH)_2+N_2+NH_3$. According to T. Curtius, lead azide is insoluble in cold water, but 100 c.c. of boiling water dissolve 0·05 grm. Boiling water slowly decomposes the salt with the formation of a non-explosive lead compound and the expulsion of hydrazoic acid. The salt is insoluble in conc. aq. ammonia; and is easily soluble in hot acetic acid with a gradual decomposition. The freshly precipitated azide is soluble in a soln. of lead acetate. J. W. Turrentine said it is easily dissolved by dil. nitric acid, and slowly, with effervescence by sulphuric acid. W. Strecker and L. Claus found that selenium monobromide reacts with lead azide suspended in benzene, forming lead chloride and selenium.

According to L. Wöhler and W. Krupko, basic lead azide can be prepared in three ways: (i) by heating the calculated quantities of lead azide and lead hydroxide under water in a sealed tube at 140° for twelve to fifteen hours, and separation of the basic azide from specifically heavier unchanged azide by elutriation. The method has the drawback that large, spontaneously explosive crystals of lead azide are liable to separate during the slow cooling of the tube; (ii) by leading a current of carbon dioxide-free air through a boiling aq. suspension of lead azide until the calculated amount of hydrazoic acid has been evolved; and (iii) by heating the requisite quantities of freshly precipitated lead hydroxide and lead azide under water on the water-bath for twenty hours. The two latter methods yield uniform products. The basic azide is less sensitive to percussion or temp. than lead azide, whilst an intimate mixture of lead azide and oxide in the proportions necessary to form the sub-azide shows the same sensitiveness as the pure azide. It is interesting to note that lead azide when mixed with 30 per cent. water has the same sensitiveness as the dry azide, whilst moist mercurous azide is scarcely less sensitive than the dry product.

T. Curtius and A. Darapsky obtained an explosive precipitate by boiling a mixture of cerium nitrate and sodium azide. Freshly precipitated cerium hydroxide dissolves in hydrazoic acid, forming a soln., which, on evaporation, gives a yellow explosive residue **cerium hydroxyazide,** probably $Ce(OH)(N_3)_2$. According to L. M. Dennis, a soln. of potassium azide gives a flocculent precipitate with a neutral soln. of a *thorium* salt: $Th(NO_3)_4+4KN_3+4H_2O \rightarrow Th(OH)_4+4KNO_3+4HN_3$, and L. M. Dennis proposed the reaction for the qualitative detection and quantitative determination of thorium either alone or in the presence of other rare earths. Yttrium, lanthanum, cerium, didymium salts furnish basic azides; uranium, and zirconium are precipitated as hydroxides, and alums behave in the same way. A. W. Browne and co-workers obtained **antimony azide,** SbN_3, using an antimony anode in the electrolysis of a soln. of ammonium azide in liquid ammonia at —67°.

T. Curtius and J. Rissom found that freshly precipitated chromic hydroxide dissolves in hydrazoic acid; and while the soln. of **chromium azide,** $Cr(N_3)_3$, is stable, it decomposes on evaporation, and L. M. Dennis obtained a precipitate of chromium hydroxide by treating a soln. of chrome-alum with potassium azide. E. Oliveri-Mandalà found that a soln. of chromic nitrate treated with 3 mols of sodium azide becomes violet and then green; but nothing separates on standing even with conc. soln. Chromium azide may be separated by means of the insoluble, and stable pyridine compound, **chromium pyridinoazide,** $[Cr(N_3)_3(C_5H_5N)_3]$, or $Cr(N_3)_3.3C_5H_5N$, which forms a green, crystalline crust and explodes violently when heated. When boiled, its conc. aq. soln. deposits mixtures of basic salts of various compositions, **chromium hydroxydiazide,** $OH.Cr(N_3)_2,2H_2O$, which is far less explosive than the original compound, being isolated. Aq. soln. containing chromium azide exhibit the green colour peculiar to complex chromium salts, and do not yield a precipitate with ammonia soln.; even when the experimental conditions are widely varied, addition of silver nitrate does not cause precipitation of the whole of the nitrogen as silver azide. E. Oliveri-Mandalà and G. Comella obtained the normal azide by evaporating the alcoholic soln. in vacuo over potassium hydroxide, and **chromium dihydroxyazide,** $CrN_3(OH)_2$, as a product of hydrolysis. Green crystals of **sodium chromium azide,** $CrN_9.3NaN_3$, were also prepared, and this salt gives a blue coloration with ammonia, and with silver nitrate, it does not form silver azide, but rather a highly explosive complex salt. This indicates that a complex anion is present—probably $[Cr(N_3)_6{}''']$, analogous with $[CrCy_6{}''']$, and $[Cr(SCy)_6{}'']$. The corresponding **chromihydrazoic acid,** $H_3Cr(N_3)_6$, has not been isolated owing, it is supposed, to its ready decomposability. L. M. Dennis obtained a precipitate of uranium hydroxide by treating a soln. of a uranium salt in a similar way. T. Curtius and A. Darapsky found that only a basic **uranium azide** was produced by evaporating a soln. of uranyl hydroxide or potassium uranate in hydrazoic acid.

T. Curtius and J. Rissom showed that the evaporation of a soln. of manganese carbonate in hydrazoic acid gives a pulverulent, non-crystalline **manganese hydroxyazide,** $Mn(OH)(N_3)_2$, which cannot be purified by re-crystallization. The product is sparingly soluble in water; it does not explode by percussion, but does so on a hot plate. L. Wöhler and F. Martin gave 203° for the explosion temp. of manganese azide. T. Curtius and J. Rissom obtained a colourless soln. of **ferrous azide** by the action of sodium azide on a soln. of ferrous ammonium sulphate; when boiled, the salt decomposes; and when shaken in air, a blood-red soln. of **ferric azide** is formed. The same salt can also be obtained directly from ferric salts. When the soln. of ferric azide is boiled, ferric hydroxide is precipitated; and, added T. Curtius and A. Darapsky, if allowed to stand in the cold, a brown **ferric hydroxyazide** is precipitated. A. W. Browne and co-workers obtained ferric azide by the electrolysis of a soln. of ammonium azide in liquid ammonia, at —67°, using an iron anode. L. M. Dennis obtained ferric hydroxide by treating iron-alum with potassium azide—*vide supra,* the analytical reactions of hydrazoic acid. T. Curtius and J. Rissom found that the evaporation of a soln. of cobalt carbonate in hydrazoic acid yields a **cobalt hydroxyazide,** $Co(OH)(N_3)_2$, and some normal **cobalt azide,** $Co(N_3)_2$. When the soln. is treated with potassium azide, crystals of **potassium cobalt azide,** $KCo(N_3)_3$, and with ammonium azide, crystals of **ammonium cobalt azide,** $NH_4Co(N_3)_3$, are formed respectively. L. Wöhler and F. Martin found the explosion temp. of cobalt azide to be 200°. Nickel behaves under similar conditions in an analogous way, furnishing **nickel hydroxyazide,** and **nickel azide,** as well as **potassium nickel azide,** $KNi(N_3)_3$, and **ammonium nickel azide,** $NH_4Ni(N_3)_3$. L. Wöhler and F. Martin found the temp. of explosion of nickel azide to be 200°. A. W. Browne and co-workers obtained nickel azide by the electrolysis of a soln. of ammonium azide in liquid ammonia, at —67°, using a nickel anode. S. Lorie prepared **cobalt diazidotetramminonitrate,** $[Co(NH_3)_4(N_3)_2]NO_3+H_2O$, by the action of sodium azide on cobalt dinitratotetramminonitrate; **cobalt diazotetramminoiodide,** $[Co(NH_3)_4(N_3)_2]I+H_2O$, by the action of potassium iodide on the corresponding nitrate; and **cobalt diazotetrammino-dithionate,** $[Co(NH_3)_4(N_3)_2]S_2O_6+H_2O$, by the action of sodium dithionate on the nitrate. Remembering that the symbol "En" is used for ethylencdiamine, $NH_2.CH_2.CH_2.NH_2$, and that the positions of the radicles in the ammino-compounds are numbered in accord with the appended scheme:



S. Lorie reported **cobalt 1 : 2-dichlorobisethylenediamineazide,** $[Co(En)_2Cl_2]N_3$, to be formed by the action of sodium azide on 1 : 2 cobalt dichlorodiethylenediamine-chloride; **cobalt 1 : 6-dichlorobisethylenediamineazide,** $[Co(En)_2Cl_2]N_3$, by the action of sodium azide on the corresponding chloride; **cobalt 1 : 6-diazidobis-ethyleneamineazide,** $[Co(En)_2(N_3)_2]N_3$, by the action of sodium azide on the corresponding dichlorodiethylenediamine-chloride; **cobalt 1 : 6-diazidobisethylene-diamine thiocyanate,** $[Co(En)_2(N_3)_2]CNS$, by the action of potassium thiocyanate on the azide; **cobalt 1 : 6-diazidobisethylenediaminedithionate,** $[Co(En)_2(N_3)_2]S_2O_6$, by the action of sodium dithionate; **cobalt 1 : 6-diazidobisethylenediaminenitrate,** $[Co(En)_2(N_3)_2]NO_3$, by the action of sodium nitrate; **cobalt 1: 6-diazidobisethylene-diaminechloroaurate,** $[Co(En)_2(N_3)_2]AuCl_4$, by the action of hydrochloroauric acid on cobalt 1 : 6-diazidodiethylenediamine azide; and **cobalt 1 : 6-diazidobis-ethylenediaminechloroplatinate** by the action of hydrochloroplatinic acid on cobalt 1 : 6 diazidoiethylenediamine azide.

T. Curtius and J. Rissom mixed a conc. aq. soln. of hydrochloroplatinic acid and potassium azide in the molar proportions 1 : 2, and on evaporation of the red soln. obtained a residue which exploded with *ein fruchtbarer Detonation,* and doubtless contained *platinum azide.* When the proportions of the original constituents were in proportions conformable with $H_2PtCl_6+8N_3K=K_2Pt(N_3)_6+2N_3H+6KCl$, what appeared to be potassium azidoplatinate was formed. On evaporation, the conc. aq. soln. exploded. By mixing ammonium azide and hydrochloroplatinic acid, and concentrating the soln. by evaporation, a very explosive residue was obtained.

§ 30. The Fixation of Atmospheric Nitrogen by Organisms

The fertility of cultivated fields and gardens is dependent upon the amount of combined nitrogen which is added as manure or fertilizer. Of course, cultivated plants require fertilizers containing other elements—phosphorus, potassium, etc.—but the problem of supplying available nitrogen is predominant. This has long been recognized. Thus, about the middle of the seventeenth century, J. R. Glauber [1] wrote :

> Deservedly may saltpetre or nitre be termed the universal subject and wonder of the world. . . . If it were not so, how comes it to be so plentifully found in all things ? . . . All these things which dung the fields and lands, and fatten them most necessarily contain in them saltpetre ; for, from this only and alone, comes all the fertility throughout the whole earth, which axiom cannot be gainsayed. . . . Having shown that nitre or saltpetre may be had from all things, *viz.*, from herbs, wood, four-footed beasts and creeping things, from birds in the air, and fishes in the water, yea, from the very elements themselves—earth, water, air, and fire—it must needs follow that it is that so much spoken of universal spirit, without which nothing can either be or live. It is the begetter and destroyer of all things, as I have demonstrated in my *Miraculum mundi* out of the most ancient philosopher Hermes. I therefore hope that nobody will any more doubt thereof or oppose himself with a perverse stubbornness against a truth so manifestly known. . . . If any one is minded firmly to cleave to his own stubborn perverseness, even Hermes himself, should he rise from the dead, would lose his labour in teaching him.

A. L. Lavoisier demonstrated that nitric acid does not pre-exist in the chalk of Roche Guyon, and Mousseaux, but is formed by the action of air. In 1796, W. Saltonstall inferred that at the instant of its escape from putrefying substances, nitrogen is oxidized by the oxygen of the air ; and P. Thouvenel produced nitrates by exposing chalk to the gases evolved from the putrefaction of animal and vegetable substances—mixtures of ammonia and air ; and he concluded :

It is demonstrated by our experiments that atmospheric air possesses all that is necessary to serve for nitrification, as well as air which emanates from putrescent bodies provided it finds matter capable of absorbing the materials.

Early in the nineteenth century the deposits of nitrates in the Peruvian desert attracted attention, and the subject was discussed by J. B. J. D. Boussingault, M. Longchamp, T. Graham, J. L. Gay Lussac, etc.—*vide*, 2. 20, 36. It was soon recognized—*e.g.* by H. Davy, J. von Liebig, J. B. J. D. Boussingault, and G. J. Mulder—that the production of nitrates in soils is at the cost of the organic nitrogen which is present. The nitrogen contained in soils is made up of ammonia, nitrates, nitrites, and mainly organic compounds. The organic matter is largely derived from the tissues of plants and animals, and is often referred to as humus. According to S. L. Iodidi, humus consists largely of proteins together with their decomposition products. There are also nucleoproteids, and non-protein substances like acid amides, and amino-acids. Under the influence of proteolytic enzymes, bacteria, or chemical agents, the proteins are decomposed first, forming allumoses, peptones, and polypeptides, and then mono- and di-amino-acids, and acid amides ; and the nucleoproteids furnish nucleins, nucleic acid, and purine and pyrimidine bases, as well as some proteins.

C. F. Schönbein thought that the nitrates in soils were produced by the union of atm. nitrogen with evaporating water to form ammonium nitrite—*vide supra*, ammonia. G. J. Mulder, S. de Luca, S. W. Johnson, and A. Houzeau attributed the nitrates to the action of ozone on the nitrogen associated with organic matter. F. Goppelsröder, and L. Carius assumed that nitrates are formed by electrical discharge in air. C. P. Collard de Martigny believed that the bases present in soils exerted a predisposing affinity on the nitrogen whereby nitrates were formed. F. A. Haarstick assumed that the iron oxides in soils stimulated the formation of nitrates ; and, according to N. A. E. Millon, the slow oxidation of alkali ulmates in the soil induces the oxidation of ammonia by contact action. N. A. E. Millon, and also F. H. Storer found that all attempts to oxidize ammonia in the wet way by ferric oxide have proved unavailing. A. Müntz and T. Schlösing first demonstrated that the nitrification in soils is the work of organized ferments, or bacteria. The production of nitrates can be arrested by raising the temp. to 100°, or by treatment with chloroform, which has but little effect on soluble ferments. R. Warington also showed that antiseptics like carbon disulphide, and phenol, as well as chloroform, are inimical to nitrification ; that where nitrification has been arrested, that process can be restarted by seeding with a substance already nitrifying ; and that light hinders the activity of the organism responsible for the oxidation of ammonia. These results were confirmed by P. P. Deherain, E. M. Davy, J. H. M. Munro, and E. Godlewsky. The biological character of the nitrification process was indicated by the work of A. Müller, J. Soyka, etc. A. Müntz and T. Schlösing isolated the bacterium—*micrococcus nitrificans*—thought to be responsible for the nitrification of ammonia in soils. R. Warington then showed that the nitrification is really the joint effect of two organisms; one converts ammonium salts into nitrites, but fails to change nitrites into nitrates even after the lapse of several years. The subsequent conversion of nitrites to nitrates is the work of another organism, although, as A. Müntz showed, the nitrites may be oxidized chemically by the joint action of the carbon dioxide and oxygen of the atm. P. F. and G. C. Frankland isolated the bacillococcus which produces nitrous acid from ammonium salts; and S. Winogradsky, the bacterium which transforms the nitrites to nitrates, but has no action on ammonium salts ; and also the one which converts ammonium salts to nitrites. W. Omeliansky failed to detect the presence of an oxydase secreted by the organism which oxidizes ammonia to nitrite either in the filtered medium or in the disintegrated bacteria. The organism which oxidizes nitrites to nitrates cannot oxidize sulphites to sulphates, or phosphites to phosphates.

S. Winogradsky emphasized the ubiquitous distribution of the bacteria concerned with nitrification; he found them in the soils of all climates; in sea-waters; in drainage waters; etc. This has also been confirmed by A. Müntz, F. Weis, P. Ehrenberg, W. Migula, A. Beddies, H. Schultz-Schultzenstein, H. S. Fremlin, F. L. Stevens and W. A. Withers, K. F. Kellermann and T. R. Robinson, A. D. Hall, H. V. von Falckenstein, P. Thomsen, K. Brandt, E. Baur, E. E. Reid, F. Diénert, G. G. Nasmith and G. P. McKay, P. Rudnik, etc. According to A. Müntz and E. Lainé, the filtration of dil. ammoniacal soln. through animal charcoal or peat is accompanied by some nitrification. F. Hüppe, W. Heraeus, R. Warington, A. Müntz, T. Leone and O. Magnanini, T. Schlösing, M. Berthelot, P. F. and G. C. Frankland, E. Chuard, O. Helm, A. D. Hall, W. Omeliansky, P. P. Dehérain, and J. Wortmann showed the dual nature of the process, for the bacteria assimilate not only nitrogen but also carbon from dil. soln. of ammonium carbonate. The work of R. Roche, St. von Bazarewsky, and G. G. A. Weber showed that the most favourable temp. for nitrification by bacteria is 25°–27°. St. von Bazarewsky, A. Koch, J. G. MacBeth and N. R. Smith, P. P. Dehérain, T. Schlosing, H. Buhlert, P. Mazé, T. L. Lyon and co-workers, and W. P. Kelley found that the nitrification process is most active near the surface of the soil, and the aeration of the soil favours the process. The presence of about 17·5 per cent. of moisture was found by A. E. Traaen, A. P. Lipman and co-workers, O. Lemmermann, R. Stewart and J. E. Greaves, J. C. MacBeth and N. R. Smith, R. Roche, W. Buddin, and W. P. Kelley to be most favourable for the nitrification, but the nature of the soil is also of influence. Other things being equal, highly acidified soils were found by E. E. Ewell and H. W. Wiley, and P. L. Lyon and J. A. Bizzell to be harmful, while basic soils are beneficial. E. Murmann, S. Machida, P. E. Müller and F. Weis, H. Fischer, J. Vogel, O. Lemmermann and co-workers, E. B. Fred, E. Polszeniusz, W. A. Withers and G. S. Fraps, W. P. Kelley, F. Miller, and T. Arnd found calcium carbonate favours nitrification, but not so magnesium carbonate; S. Dezani, and J. W. Paterson also found gypsum favourable, but not to the extent of calcium carbonate. J. G. Lipman, J. Crochetelle and J. Dumont, found sodium carbonate harmful, sodium chloride less so, and sodium sulphate still less so. P. L. Gainey, C. de Briailles, and A. Pagnoul found carbon disulphide to be harmful; and P. Cacciari, that naphthalene is also harmful; while A. Koch and A. Oelsner observed no ill-effects with tannin or pine resin. J. E. Greaves noted that arsenic stimulated the activity of the bacteria, and C. Montanari, and G. Leoncini, likewise salts of manganese and of the heavy metals. S. Winogradsky, W. Omeliansky, and O. Meyerhof found that relatively small proportions of glucose, peptone, asparagin, glycerol, urea, sodium acetate, sodium butyrate, and ammonia act deleteriously on both the nitrite and nitrate ferments. J. G. Lipman and P. E. Brown found nitrification dependent on the conc. of the ammonium salts present; R. Perotti, that the speed of nitrification follows a logarithmic curve; and W. Omeliansky, and O. Meyerhof, that a high conc. of ammonia or of nitrite is harmful; the optimum conc. of the nitrite is about 0·05 per cent. with a second optimum with 0·1 per cent.—over 0·3 per cent. interferes with the progress. E. Rolants observed that 0·2 grm. of free ammonia per litre is completely nitrified; but with 0·5 grm. per litre, the process is inhibited, and E. Boullanger and L. Massol, that the process is at a standstill with 30–50 grms. of ammonium carbonate per litre, but works well with 2 grms. per litre. Attempts have been made by A. Müntz and E. Lainé, E. Boullanger and co-workers, H. L. R. Lunden and C. T. Thorssell, and others to utilize the bacterial oxidation of ammonia to nitrates; but the reactions are so slow, the space required for handling the enormous bulk of dil. soln. required is so large; and the cost of evaporating these dil. soln. is so great that the results on an industrial scale are not likely to be profitable. For the denitrification of nitrates by bacteria, *vide* the formation of nitrogen, ammonia, and nitrites. F. Löhnis has discussed the nitrification and denitrification of soils. According to P. Haupt, and A. Tschirch, the absorption of atm. nitrogen by leguminous plants is due to electronic action, and this view was supported by the work of E. Hiedemann, and F. Fichter and R. Suter. D. Burk discussed the free energy of the fixation of nitrogen by living organisms.

J. B. J. D. Boussingault tried if certain fungi—*e.g.* the *penicillium*—can fix atm. nitrogen, but the results were negative. On the other hand, F. Sestini and G. del Torre, J. G. Lipman, W. P. Latham, E. I. Fulmer and L. M. Christensen, C. Ternetz, K. Puriewitsch, and K. Saida obtained positive results. Numerous investigations have been made on this subject. H. Davy said that the earthy constituents of soils are alone unable to fix the nitrogen as plant food. M. Berthelot, however, was able to prove that the bacteria in soils are able to enrich the soil by fixing atm. nitrogen. This result was confirmed by the work of P. P. Déhérain and L. Maquenne, E. J. A. Gautier and R. Drouin, T. Schlösing, A. Pagnoul, B. Tacke, H. Immendorff, V. Alpe and A. Menozzi, M. W. Beyerinck and A. van Delden, M. Gerlach and I. Vogel, E. von Freudenreich, A. Koch, S. Winogradsky, F. Löhnis and T. Westermann, etc. It has long been known that leguminous plants—peas, beans, clover, lupins, alfalfa, etc.—enrich the nitrogen content of soils. These plants have the remarkable power of producing comparatively large quantities of nitrogenous proteids even when nitrogen compounds are absent from the soil. Plants like the gramineæ can do this only when nitrogenous food is at their disposal in the soil itself. The fact was mentioned in 1808 by A. D. Thaer, and H. Davy said that the nitrogen contained in peas and beans is derived from the atmosphere. These observations were abundantly confirmed by J. B. J. D. Boussingault, G. Ville, J. B. Lawes and J. H. Gilbert, H. Hellriegel and H. Wilfarth, C. Schulze, M. H. Maercker, E. Gatellier, W. O. Atwater, J. Lutoslawsky, P. Wagner, and T. Schlösing and E. Laurent. Nodules on the roots of these plants were studied by M. Malpighi, J. Dalechamps, P. Boccone, A. P. de Candolle, L. C. Treviranus, H. Lachman, J. Erikson, A. Cornu, T. Dyer, E. Warming, L. Kny, A. B. Frank, E. E. Prillieux, etc. The nodules on the rootlets of a *phaseolus* are illustrated by Fig. 55. A magnified cross-section is shown in Fig. 56. They were considered to be a pathological condition, and G. Gasparrini, and M. Woronin observed that the parenchyma cells of the nodules contained bacteria in short rod-like forms. F. Schindler suggested that these bacteria—which M. W. Beyerinck called *bacterium radicicola ;* and A. B. Frank, *rhizobium leguminosarum*—live with the plant in a kind of partnership, or symbiosis—from σύν, with ; βίωσις, living. The bacteria live as guests in nodules in the roots of their host, and probably in the neighbouring soil. The symbiotic bacteria work up the nitrogen of the atmosphere in a form available as food for the plant on which they live. These bacteria are present in the soil, they penetrate the root hairs of legumes, grow into the cortex

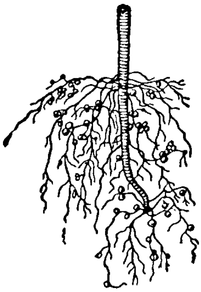

FIG. 55.—Tubercles or Nodules on Root of Bean Plant.

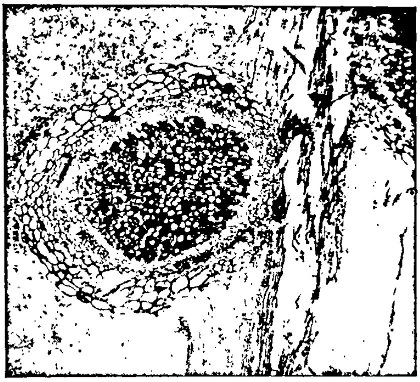

FIG. 56.—Cross-section through the Root-nodule of the Bean.

of the roots, and induce the formation of the tubercles. The bacteria multiply and pass into the tissue of the developing tubercle. These observations were established by the work of A. Prazmowsky, H. Hellriegel, R. Greig-Smith, G. E. Mattei, L. Montemartini, H. Möller, Z. Kamerling, B. L. Issatschenko, M. W. Beyerinck, A. Sperlich, A. Trotter, E. R. Spratt, L. Koch, G. Nicolas, E. Jülg, J. Brunchorst, O. Mattirolo and L. Buscalioni, A. Tschirch, A. B. Frank, E. Warming, P. Schürhoeff, P. E. L. van Tieghem and E. Douliot, G. F. L. Sarauff, W. B. Bottomley, O. Zinsser, J. Golding, J. Levy, E. Bréal, L. Albert, A. L. Whiting, J. Stoklasa, P. P. Dehérain and E. Demoussy, F. Noble and co-workers, etc. E. Kayser and H. Delaval observed that the presence of a radioactive uranium mineral increased the activity of nitrogen-fixing bacteria. A. W. Bosworth and co-workers observed that ammonia is produced by the human tubercle bacillus.

The chemical actions which occur in the fixation of nitrogen under these conditions have been studied by L. Hiltner, but the results are indefinite. Many soils are very deficient in the bacterium radicicola, and experiments have been made by numerous workers—A. P. Aitken, C. Barthel, G. Bredmann, H. R. Christensen, R. Combes, A. Eichinger, H. von Feilitzen and co-workers, A. B. Frank, E. B. Fred, W. Golte, E. Grabner, L. Hiltner, K. F. Kellerman and co-workers, T. Imasehki, G. Kock, A. Kühn, E. Laurent, C. P. Lipman and L. W. Fowler, F. Löhnis and S. Suzuki, M. H. Märcker and H. Steffeck, N. Makrinoff, O. Mattirolo and M. Soave, G. T. Moore, F. Noble and co-workers, V. Peglion, T. Remy, J. Schuloff, J. Simon, N. Strampelli, B. Tacke, A. Teichinger, E. Teisler, J. A. Völcker, etc.—with the object of impregnating soils with the bacteria so necessary for the full development of leguminous plants. A number of cultures of these bacteria have been placed on the market so that soils can be readily inoculated, For example, there are F. Noble and L. Hiltner's *nitragen ;* J. Simon's *azotogen ;* G. T. Moore's culture, *nitrobacterine ; bacterized peat ;* etc. In a way, the results have been fairly satisfactory for certain crops when peptones and glucose were added to the water in which the nitrifying bacteria are distributed for spreading on the soil.

The early workers—S. Hales, J. Ingenhousz, and J. Priestley, for example, *vide* **1.** 3, 7—on the assimilation of food by plants were more particularly concerned with the changes produced in the atmosphere surrounding the plant, and little progress could be made until the composition of air and water had been established. J. Priestley had the opinion that free nitrogen could be assimilated by the higher plants ; while N. T. de Saussure, on the contrary, thought that nitrogen was given off by them. He also concluded that plants derive their food from air and water—the nitrogen being derived from the ammonia and nitrogenous matters in the soil ; and the mineral constituents, also from the soil. The evidence adduced by J. B. J. D. Boussingault, J. B. Lawes and co-workers, was one time taken to prove that green plants, without the aid of bacteria, cannot fix elementary nitrogen from the atm. G. Ville, however, contended that some green plants do possess this power, and T. Jamieson, E. Mameli and G. Pollacci, B. Moore and co-workers, F. B. Wann, and C. B. Lipman and J. K. Taylor showed that wheat, barley, and some other plants can gain nitrogen at the expense of atm. air without the nitrogen being first fixed by bacteria, and then passed on to the plant ; peas cannot fix nitrogen without the aid of bacteria ; while the *Bromus villosus* can do so to a slight extent. It is assumed that the fixation of nitrogen occurs in the cells of the green leaves. The physiological action is discussed in works by A. Fischer, K. W. Jurisch, E. Abderhalden, H. Frölich, G. Stahel, C. Ternetz, P. Haupt, etc.

E. C. C. Baly and co-workers [2] showed that soln. of nitrates and carbonic acid are respectively converted into nitrite and formaldehyde in ultra-violet light, and these products then react to form formhydroxamic acid ; this acid then combines with more photosynthesized formaldehyde to give a variety of products —*e.g.* glyoxaline, free and substituted α-amino-acids, and substances of an alkaloidal nature. Methylamine and pyridine are produced by the action of photochemically activated formaldehyde on ammonia. According to O. Baudisch, cholera bacilli rapidly reduce nitrates to nitrites, and the velocity of the reaction is dependent on the bacterial iron content. Dextrose in alkaline soln. reduces nitrites, but not nitrates, and then only in the presence of traces of iron. Ferrous hydrocarbonate, or hydroxide, does not reduce alkali nitrates even at 100° in the absence of oxygen ; the presence of oxygen, however, causes immediate reduction to nitrite, and there is a direct relation between the amount of oxygen dissolved in the water and the amount of nitrite formed. This " fertilization " process involves the production of a peroxidic iron compound, nitrite, and the reactive intermediate substance potassium nitrosyl, KNO. The latter substance reacts with aldehydes with the formation of hydroaximic acids, OH.N : N.OH. The magnetic properties of the peroxide are directly related to its great chemical activity. The action of potassium pentacyanoperoxoferrate, $K_3[FeO_2(NC)_5]$, in behaving as an oxygen carrier and activator is likened to a simple type of respiration. Whilst light of long wave-length brings about the formation of an alkaline aquobase from potassium ferrocyanide soln., the reduction of alkali nitrates is effected only by light of short wave-length. In summer sunlight, alkali nitrates can be reduced to nitrite in a short time if small quantities of complex salts, *e.g.*, potassium ferrocyanide, are present. Formaldoxime and formaldehyde in sunlight form cyclic nitrogen compounds which contain pyridine and pyrrole rings and give the typical alkaloidal reactions. An aq. soln. of acetaldoxime and formaldehyde when exposed to sunlight gives a thick, dark brown syrup which has not been investigated. Nitromethane also unites with formaldehyde under the influence of light, or in weakly alkaline soln., isonitrobutylglycerol being formed intermediately. The illumination of alkali nitrates with daylight in the presence of formaldehyde yields gases agreeing qualitatively with those formed by soil bacteria, and (in the presence of iron salts) formhydroxamic acid and formaldoxime. It is possible that many soil bacteria and also green leaves utilize nitrous oxide from the air for nitrogen nutrition. Although at considerable altitudes, or by the influence of silent electric discharges, carbon dioxide can be reduced to formaldehyde, which may then react with nitrous oxide from atm. nitrogen and oxygen to yield formhydroxamic acid, it is thought possible that the reduction can be effected by sunlight at sea-level without the aid of chlorophyll. N. R. Dhar and R. P. Sanyal found that while ultra-violet light is more effective in certain photosyntheses, yet tropical sunlight contains a number of rays which can effect the synthesis of complex compounds from simple substances. Methylamine, which is formed in about 12 hrs. when ammonia and formaldehyde are exposed to tropical sunlight, passes into a number of complex substances of the alkaloid type. In violet-light, nitrogen and oxygen combine to form nitrogen oxides. The difference between the action of sunlight and ultraviolet light in promoting photosynthesis is one of degree rather than of kind.

The nitrogen cycle.—All living matter, and the waste products of animals contain considerable quantities of combined nitrogen. This element is a necessary constituent for the growth of living organisms. During the decay of organic matter through the agency of bacteria, part of the nitrogen finds its way back to the atmosphere, and part passes directly into the soil to be absorbed by plants. Animals cannot assimilate free nitrogen, and they are accordingly dependent upon the plants for their supply ; nor can the plants usually obtain the nitrogen they require direct from the atmosphere. Most plants get their nitrogen from the soil where it is present in the form of nitrates, ammonium, or other complex compounds. The organic matter in the soil is attacked by bacteria of various kinds, and part is converted into nitrates and part into free nitrogen. A certain amount is brought back from the atmosphere, during rain storms, where it has been oxidized into ammonium nitrate by electric discharges. These supplies of available nitrogen, however, do not suffice to maintain the fertility of cultivated soils. It is therefore necessary to make good the constant draining of the available nitrogen by the cultivated plants. This is done by allowing nitrogenous matter —manures—to decay in the soil, or to add to the soil a mixture—fertilizer—containing available nitrogen and other plant foods. The processes involved in the circulation of nitrogen in nature may be summarized in the scheme :

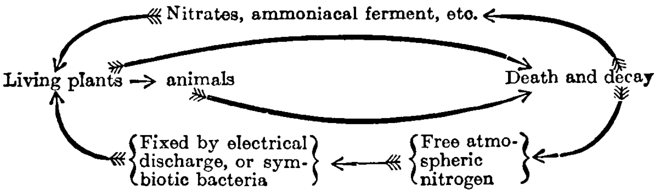

FIG. 57.—The Nitrogen Cycle.

The idea has been expressed in a more romantic way. To-day a nitrogen atom may be throbbing in the cells of the meadow grass ; to-morrow it may be pulsating through the tissues of a living animal. The nitrogen atom afterwards may rise from decaying animal refuse, and stream to the upper regions of the atmosphere, where it may be yoked with oxygen in a flash of lightning and return as plant food to the soil in a torrent of rain ; or it may be directly absorbed from the atmosphere by the soil, and there rendered available for plant food by the action of symbiotic bacteria. Thus each nitrogen atom has doubtless undergone a never-ceasing cycle of changes through countless æons of time.[3]

§ 31. The Fixation of Atmospheric Nitrogen by Direct Oxidation

The consumption of nitrogenous matters in the cultivation of lands cannot be made good by the nitrogen compounds formed by natural processes. Nature's way of restoring nitrogen to soils is by bacterial action, and electrical discharge in the atmosphere, which cause the union of oxygen and nitrogen, and, according to J. von Liebig,[1] this results in the production of about 10·3 to 16·2 lbs. of combined nitrogen per acre per annum. B. Moore also has shown that it is possible that some fixation occurs by the action of solar rays. The development of agriculture is largely dependent on the cheap production of nitrogen in a form available for plant food. The cultivation of wheat, for example, is largely dependent upon nitrogenous manures. Not many years ago, the supplies of available nitrogen were derived from the Chilean and other natural deposits of nitrates; and the ammoniacal salts obtained as a by-product in the manufacture of coal-gas, and coke. The production of nitrates by bacterial action, and in nitre-plantations—2. 20, 36—is utterly inadequate to supply the growing needs of agriculture when supplemented by animal excrementa and refuse, and sewage sludge. Although the nitre beds of Chile and Peru contain millions of tons of nitre, yet the outlook was not hopeful because it was estimated that the beds would be approaching exhaustion in about a century. Most of the nitre is used as a fertilizer for wheat, etc. Wheat is the staple food of the white races. Consequently, W. Crookes could say in 1898, " The fixation of nitrogen is vital to the progress of civilized humanity, and unless we can class it among the certainties to come, the great Caucasian race will cease to be foremost in the world, and will be squeezed out of existence by races to whom wheaten bread is not the staff of life." The problem has since been solved. The atmosphere contains about 4×10^{15} tons of nitrogen, so that there are about 20 million tons of nitrogen over each square mile of the earth's surface; this is over 30 times that produced per annum as Chile saltpetre and by-product ammonia. There is therefore present at hand an enormous supply from which the nitrogen can be borrowed for the preparation of plant food. The supply is inexhaustible because, in due course, it is returned to the atmosphere as elemental nitrogen by the operation of nature's perpetual cycle.

Just as during the Napoleonic wars, when the French ports were closed, the need for nitrates for the manufacture of gunpowder stimulated the beleaguered French to cultivate nitre-plantations (2. 20, 36), so also during the 1914–18 war, the need for nitrates for the manufacture of explosives stimulated the beleaguered Germans to develop methods for the fixation of atm. nitrogen in the form of nitrates. As a result, in 1917, they were making nitric acid from atm. nitrogen at the rate of 320,000 tons per annum, whereas in 1914, only one-fifth of this amount was produced. Otherwise expressed, the nitrogen fixation processes contributed only 4·5 per cent. of the world's consumption of nitrates and ammonia in 1912; this had increased to 43 per cent. in 1920; and now, fixation processes furnish the largest proportion of the world's requirements.

Several solutions of the problem so clearly stated by W. Crookes have been devised, some of these processes are now competing industrially, others are a little more costly, and are in consequence not in operation. The more important ways of fixing atm. nitrogen are: (i) The direct oxidation of nitrogen to its oxides so as to furnish nitric acid or nitrates, as typified in the arc processes; (ii) The direct combination of nitrogen with hydrogen to form ammonia as typified by F. Haber's process—*vide supra;* (iii) The absorption of nitrogen by the metals which subsequently form ammonia when treated with water as typified by O. Serpek's process —*vide supra;* (iv) The absorption of nitrogen by carbides as exemplified by the cyanamide process of A. Frank and N. Caro. More nitrogen is fixed by this process than by any other one. (v) The conversion of atm. nitrogen into cyanides as exemplified by J. E. Bucher's process; and (vi) The oxidation of nitrogen during the combustion of coal gas or natural gas as proposed in F. Häusser's, and O. Bender's processes.

About 1775, J. Priestley[2] passed a series of electric sparks through atm. air confined in a suitable vessel over water coloured purple by a decoction of turnsole or archil. He found:

> The most important though least expected observation was that the upper part of the liquor became red, and in proportion as the red extended so did the liquid rise in the vessel, diminishing the space in which the sparks were passing. He found that the air contracted one-fifth of the whole space, after which more sparking produced no sensible effect.

It was at first thought that fixed air—carbon dioxide—was produced, but when H. Cavendish repeated the experiment, the absence of any signs of turbidity was taken to prove that carbon dioxide was not produced by the electrification of atm. air. H. Cavendish then proved that the product of the action is nitrous or nitric acid. In his experiments on the production of water by the explosion of mixtures of inflammable air (hydrogen) and common air, H. Cavendish found that if a mixture of oxygen and hydrogen is exploded the dew which results is not pure water, but water containing nitric acid, which when neutralized with alkali and evaporated, furnished crystals of nitre. This result was embarrassing, for if water and water only is derived from the explosion of hydrogen and common air, in which the contained oxygen is alone consumed, why is water not derived, *à fortiori*, when the nitrogen of the atm. is excluded, and when the elements oxygen and hydrogen are exploded in their just proportions with each other? Whence comes the nitric acid? In January, 1783, H. Cavendish proved that the nitric acid is derived from the nitrogen of the atmosphere, and that if the hydrogen and oxygen be properly purified, no acid is formed. By gradually increasing the proportion of nitrogen added to a mixture of hydrogen and oxygen, the quantity of nitric acid is increased, but there is a limiting value, since when the proportion of nitrogen approaches that of air, the heat produced by the explosion is so much diminished as to be incapable of determining the formation of nitric acid, and water alone is formed. H. Cavendish also showed that by passing an electric spark repeatedly through a mixture of atm. air and oxygen, confined in a bent glass tube by columns of mercury and soap-lees, nitric acid is formed, which, uniting with the alkali of the soap-lees, forms nitre. The process is slow and tedious, and failed in the hands of M. van Marum and P. van Trootswyk in Holland, and of A. L. Lavoisier, and G. Monge in France. In consequence, it was repeated three times under H. Cavendish's own directions before a committee of the Royal Society, and the result fully established.

The fixation of nitrogen by electrical discharges.—H. Davy[3] studied the formation of nitric acid during the electrolysis of water in the presence of air— **1.** 3, 6—and C. F. Schönbein explained this on the assumption that ozone is first formed, and that this attacks the nitrogen, forming nitrogen peroxide; but

L. Carius showed that ozone does not attack nitrogen either at ordinary or at elevated temp. R. Böttger, A. Perrot, and H. Buff and A. W. Hofman found that induction sparks quickly form nitrous fumes in dry or moist atm. air. G. Meissner said that only ozone is formed by the spark or silent discharge in dry air, but in moist air, nitrogen peroxide is formed. He said that ozonized air passed through water produces nitric acid, but this statement awaits verification. The formation of nitric acid by the action of the silent discharge on air passing through an ozonizer was noted by J. B. Lawes and co-workers, P. Hautefeuille and J. Chappius, C. F. Harding and K. B. McEachron, H. Spiel, E. W. von Siemens and J. G. Halske, W. Löb, M. Berthelot, S. Cloez, S. de Luca, R. Sellentin, and J. von Kowalsky. A. Findlay likewise observed the formation of nitric acid and during the action of Tesla's brush discharge on a mixture of moist oxygen and nitrogen. A. Makowetzky used an apparatus consisting of an H-tube containing dil. sulphuric acid. One limb contained the platinum electrode, through which the current passed into the acid ; the gas evolved at it was collected separately. Above the surface of the acid in the other limb, which was closed so that the gaseous products could be collected, the second electrode was placed. The arc was formed between this second electrode and the surface of the dil. acid. The second electrode was sometimes a water-cooled platinum tube, sometimes a Nernst glower, which was allowed to become hot. When the arc is formed in an atm. of nitrogen using the liquid surface as anode and a hot cathode, the only products are hydrogen and a little ammonia. When the current is reversed, oxygen, hydrogen, hydrogen dioxide, ammonia, and nitric acid are formed. The hydrogen dioxide is formed at the surface of the liquid owing to the very large cathode fall of potential. The gas at the surface of the liquid is almost entirely steam, which is probably decomposed into hydrogen dioxide and hydrogen ; as much as 9 millimols of the former per 1000 coulombs were found. The yields of ammonia and nitric acid are greatest with about 0·04 ampere (about 2 millimols per 1000 coulombs), and they appear to be formed throughout the length of the arc. K. B. McEachron[4] studied the form of the containing vessel on the production of nitric oxide by the high-voltage electric discharge. G. M. Schwab and S. Loeb obtained nitric oxide by the action of a cold, direct current discharge with an oxide cathode on a mixture of nitrogen and oxygen at 6 mm. press. It is assumed that the greater part of the energy taken from the oxygen serves to activate the nitrogen by impact of the oxygen ions on the nitrogen mols., whilst the energy absorbed by the latter for which the absorption law applies is, under the experimental conditions, only a small part of the current energy, which is mainly lost by reflection from the electrodes.

The first serious attempt to utilize H. Cavendish's reaction for burning atm. nitrogen was made in 1859 by L. J. P. B. Lefebure. She obtained a patent for making nitric acid by passing sparks through air, and absorbing the product in alkali-lye ; but the process did not come to anything. In 1880, W. Spottiswoode and J. F. Moulton observed that a flame is excited by means of an alternating current, and W. Crookes, in 1892, showed that the effect is due to the burning of the nitrogen. He said :

> Nitrogen is a combustible gas ; that is to say, a mixture of nitrogen and oxygen (atmospheric air) will under certain conditions burn with a flame, and production of nitrous and nitric acids. The reason why, when once nitrogen is set on fire, the flame does not spread throughout the whole atmosphere and deluge the world in a sea of nitric acid, is that the igniting-point of nitrogen is higher than the temperature produced by its combustion, and therefore the flame is not hot enough to set fire to the adjacent gas. The temp, is a little higher than that of a good blow-pipe flame, easily melting fine platinum wire. The hot gases rising from a flame have a strong odour of nitrous acid, and when it is produced in a closed globe, the interior rapidly fills with red gases.

In 1897, Lord Rayleigh isolated argon from atm. air by confining a mixture of 9 vols. of air and 11 vols. of oxygen in a glass globe in which the electric flame was developed—*vide* argon. He obtained a yield eq. to 49 grms. of nitric acid per kilowatt hour. By using an alternating current of 60 periods per second and 8000 volts, A. McDougall and F. H. Howles obtained a yield of 65 grms. of nitric acid per kilowatt hour. J. de Kowalsky increased the yield still further by using a current of 0·05 amp., 50,000 volts, and 6000–10,000 periods per sec.; while C. S. Bradley and D. R. Lovejoy obtained a yield of 88 grms. of nitric acid per kilowatt hour by substituting arcs quickly torn away from the electrodes so as to furnish a series of isolated sparks or arcs.

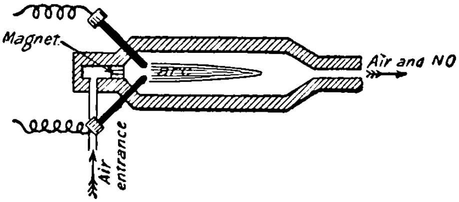

FIG. 58.—E. W. von Siemens and J. G. Halske's Experiment.

In E. W. von Siemens and J. G. Halske's experiment, Fig. 58, nitrogen was burnt by passing air through a powerful electric arc spread over as great a surface as possible by means of an electromagnet. In 1903, K. Birkeland and S. Eyde established a factory, the Norsk Hydroelektrisk Kuaelstofaktieselskab, at Notodden, Norway, for the fixation of atm. nitrogen as nitrites and nitrates. It was found that with the ordinary arc-flame, the hot space is relatively small and the conditions for rapid cooling are bad; with intermittent sparking or arcing, the conditions for rapid cooling are better. The arc is spread out or dispersed by a magnetic field, and accordingly, the air in the arc itself is very hot; but just outside the arc, the air is comparatively cool, so that the nitrogen oxides formed in the arc are cooled, at once, just outside the arc. Hence, when air is heated in the electric arc in order to oxidize the nitrogen, short thick arc flames are to be avoided. In 1905, A. A. Naville and P. A. and C. E. Guye showed that if the nitrous oxide be allowed to accumulate, the rate of oxidation per unit of energy employed is greatly diminished; and in consequence, (1) the oxidized air should be removed as speedily as possible from the sparking chamber, and (2) the sparking chamber should be as small as possible to hinder the diffusion of oxidized air into the fresh air entering. J. Brode, F. O. Anderegg and co-workers, K. B. McEachron and co-workers, and A. Geitz studied the oxidation of nitrogen in the high-tension arc flame.

M. Berthelot found that when a mixture of nitrogen and an excess of oxygen is sparked over alkali-lye, an excess of nitrite over nitrate is always produced. This would not be the case if the nitrogen was oxidized to nitrogen peroxide. He accordingly supposed that the two gases first combine to nitric oxide, and that this is then oxidized to nitrous anhydride, which in turn is partly oxidized to nitric peroxide, and part is absorbed as such. Nitrogen is so stable at ordinary temp. that instead of exhibiting a tendency to oxidize, the oxides tend to break down into their elements. The first step in the oxidation is to convert the nitrogen to nitric oxide. The nitric oxide is subsequently converted by the atm. oxygen into nitrogen peroxide. W. Muthmann and H. Hofer first attempted to measure the equilibrium conditions of the reversible reaction $N_2+O_2\rightleftharpoons 2NO$, at different temp., employing a high-tension alternating current arc between platinum electrodes. The measurements were subsequently extended by W. Nernst and his co-workers, K. Finckh, and K. Jellinek, by F. Haber and co-workers, and others. The equilibrium constant, K, for the reaction: $N_2+O_2\rightleftharpoons 2NO$, is $[O_2][N_2]K=[NO]^2$. It is of course probable that if the temp. were to be raised high enough, the mols. of nitrogen and oxygen would be dissociated into atoms; the endothermal reaction $N_2+O_2=2NO$ would become exothermal $N+O=NO$; and the conc. of the nitric oxide thereafter diminish with rise of temp. If x denote the percentage of nitric oxide by vol. at equilibrium, starting with air containing 79·2 per cent. of nitrogen and 20·8 per cent. of oxygen, $x^2=K(79{\cdot}2-\tfrac{1}{2}x)$. Then, W. Nernst and fellow-workers showed that with air,

0° .	1538°	1604°	1760°	1922°	2307°	2402°	2627°	2927°
x Obs.	0·37	0·42	0·64	0·97	2·05	2·23	—	—
x Calc.	0·35	0·43	0·67	0·98	2·02	2·35	3·18	4·39

where the calculated values are derived from the equation $\log_{10}(K/K_1) = Q/2{\cdot}3R\{(T_1-T)/TT_1\}$, when the conc. of nitric oxide from air at 2200° K. is 0·99 per cent. The formation of nitric acid is an endothermal process, and these results are in agreement with the general law that a rise of temp. displaces the equilibrium in a direction which favours the formation of an endothermal compound. The observed values of K at atm. press. are :

°K. .	1811°	1877°	2023°	2033°	2195°	2580°	2675°
log K Obs.	−4·08	−3·97	−3·59	−3·60	−3·23	−2·57	−2·49
log K Calc.	−4·13	−3·95	−3·59	−3·57	−3·23	−2·58	−2·45

where the observed values are calculated from I. W. Cederberg's expression $\log K = -9444T^{-1}+0{\cdot}000372T^{10{\cdot}75}+0{\cdot}399$. W. Nernst gave $\log K=1{\cdot}63-9450T^{-1}$; and also $\log K=1{\cdot}09-9452T^{-1}$; J. Boner, $\log K=1{\cdot}60-9450T^{-1}$; W. G. Shilling gave $\log K=-9397T^{-1}-1{\cdot}75 \log T+0{\cdot}00680T-0{\cdot}0_5297T^2+0{\cdot}0_9442T^3+1{\cdot}6$. C. P. Steinmetz, $\log_{10} K=1{\cdot}048-9380T^{-1}$. In the case where a mixture of equal vols. of nitrogen and oxygen is used, $K(50-\frac{1}{2}x)^2=x^2$, or, since x is small, $x=50\sqrt{K}/(1+\frac{1}{2}\sqrt{K})$, very nearly, and with air, $x=40{\cdot}8\sqrt{K}/(1+0{\cdot}52\sqrt{K})$, very nearly. This makes the yield with a mixture of equal vols. of nitrogen and oxygen about 18 per cent. greater than is the case with air. The gases leaving the combustion chamber must be cooled to ordinary temp. before they can be analyzed. Hence, if the cooling takes place slowly, the high temp. equilibrium will be displaced, forming a new state corresponding with the temp. at which the velocity of the reaction is negligibly small. Hence, it is imperative to cool the gases so rapidly that there is no time for a change from the high temp. equilibrium to that of a new state. H. V. Tartar and M. F. Perkins found that with a high tension arc, and a gas velocity through the arc of 330 litres per hour, the equilibrium, approached from both sides, at atm. press., is that shown in Fig. 59. M. le Blanc and W. Nüranen found that below 300°, the reaction is bimolecular, and above that temp., a unimolecular reaction sets in. In the former case, k_1 denotes the velocity constant for the formation of nitric oxide, and k_2, that for the decomposition of nitric oxide. If the rate of formation of nitric oxide be dx/dt, then, if C_1 and C_2 respectively denote the vol. percentages of nitrogen and oxygen gases, and x, that of nitric oxide, $dx/dt=K_1(C_1-\frac{1}{2}x)(C_2-\frac{1}{2}x)-k_2x^2$. C. P. Steinmetz gave $\log_{10} K_1 =0{\cdot}161+5{\cdot}731\times10^{-3}T-9380T^{-1}$; and $\log_{10} k_2=9{\cdot}113 +5{\cdot}731\times10^{-3}T$. K. Jellinek has measured the velocity constants, k_1 and k_2, and found them to be much affected by variations of temp. The time required for half the decomposition of nitric oxide into nitrogen and oxygen approximates to $t_2=1/k_2$; and the time needed for half the theoretical production of nitric oxide is $t_1=1{\cdot}36k_1^{-\frac{1}{2}}k_2^{-\frac{1}{2}}$. K. Jellinek found, for atm. press.,

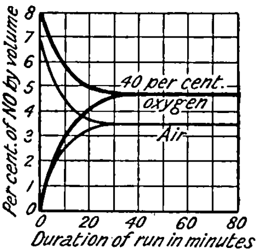

FIG. 59.—Equilibrium in the Oxidation of Nitrogen with Air, and Oxygen-enriched Air.

k_2 .	$1{\cdot}74\times10^{-7}$	$2{\cdot}33\times10^{-1}$	$1{\cdot}20\times10^3$	$5{\cdot}55\times10^4$	$6{\cdot}98\times10^7$	$5{\cdot}48\times10^{10}$
Time	81·62 yrs.	1·26 days	2·08 min.	5·06 sec.	$1{\cdot}06\times10^{-2}$ sec.	$3{\cdot}45\times10^{5}$ sec.

Here, at the absolute temp. indicated, the period of time is that required for the formation of half the possible conc. from air. On the other hand, the periods of time required for the complete decomposition of half a given quantity of nitric oxide at atm. press. are $7{\cdot}35\times10^3$ min. at 900° K.; $5{\cdot}80\times10^2$ min. at 1100° K.; 44·3 min. at 1300° K.; 3·3 min. at 1500° K. and $1{\cdot}21\times10^{-3}$ min. 2100° K. E. Briner and co-workers represented their results by $\log (C^2_{\mathrm{NO}}/C_{\mathrm{N_2}}C_{\mathrm{O_2}})=1\cdot63-9452T^{-1}$; and S. W. Saunders obtained fairly good results with $\log K_p=1\cdot0-9452T^{-1}$. C. P. Steinmetz has made more elaborate calculations. The results show that the state of equilibrium, $N_2+O_2\rightleftharpoons 2NO$, is attained at very high temp. in a very short time; and that below 1000°, the rate of decomposition of nitric oxide is so slow as to be negligible for industrial purposes. Hence, assuming that the reaction is purely thermal, the best results with air should be obtained by working above 3000°, and cooling below about 1000° with the utmost celerity. The most convenient way of obtaining the required high temp. is the electric arc, and no other method has been successful. J. Boner studied the results obtained in the oxidation of nitrogen to nitric oxide with platinum as a catalytic agent, and also when the platinum is associated with the alkaline earths as promotors.

The only conclusion W. Muthmann and H. Hofer, H. V. Tartar and M. F. Perkins, and W. Nernst could draw from the close agreement between the observed and calculated values of x, was that the reaction is purely thermal in that the reaction observed is solely produced by the absorption of heat; and there is no deviation from the law of mass action due to special electrical effects; and H. V. Tartar and M. F. Perkins obtained no evidence that a reduction of press. would increase the efficiency of the process. M. le Blanc and W. Nüranen found that the equilibrium constant, K_1, was not affected by changes in the conc. of the initial mixture ranging from 3·2 to 87·1 per cent. of oxygen. A. Grau and F. Russ observed that the value of K increased with increasing proportions of oxygen, and attributed this to the increased temp. of the arc, because the electrical energy in watts required to maintain the arc simultaneously increased. They assumed, therefore, that an equality of watt-consumption was an approximate criterion of the equality of the temp. of the arc; and they found that the values of K were in harmony with the assumption that the process is purely a thermal one. They also found that the equilibrium in the high-tension arc is not influenced when the press. changes from 761 to 847 mm. in harmony with the law of mass action for reactions in which the number of mols. does not change. F. Förster, and H. Lee and A. Beyer found the yields were practically identical with the direct and alternating current discharges, and hence concluded that reaction in the arc is not affected by electrical influences, but is purely a thermal process. F. Haber and co-workers obtained much larger yields of nitric oxide than were obtained by W. Nernst, and by extrapolation, the results would represent impossibly high temp.—say, 5000° K. Thus, while W. Nernst obtained 5 per cent. of nitric oxide at 3200°, F. Haber and A. König found that the percentage amount of nitric oxide formed increases with current up to a maximum, and then is not affected by a further increase of current. They worked with press., ranging from 40 to 200 mm. The greatest yield of nitric oxide was obtained at 100 mm. press.

Oxygen initially present .	20·9	48·9	44·4	75·0	81·7 per cent.
Nitric oxide produced .	9·8	14·4	14·3	12·77	12·1 „ „

Hence, some influence must be at work other than the purely thermal change represented by the equilibrium $N_2+O_2\rightleftharpoons 2NO$. E. Briner and E. L. Durand, and P. A. Guye consider that our knowledge of the high temp. equilibrium of nitric oxide is based on values extrapolated from observation at much lower temp. and that subsidiary reactions such as dissociation of nitrogen and oxygen to atoms or ions would explain the production of greater proportions of nitric oxide than are predicted by the extrapolation.

M. Berthelot, in 1877, stated that nitrogen and oxygen do not form nitrogen oxides under the influence of the silent discharge, but in 1906, he showed that the gases do unite under this condition. H. Fischer observed that with a Tesla current of 10,000 volts, a mixture of nitrogen and oxygen furnishes small quantities of nitrogen pentoxide, no nitric oxide, and a yield of ozone which increases with increasing conc. of oxygen. A. Gunther-Schulze observed that nitrogen and oxygen react only slightly in the glow discharge, and C. Boissonnas studied this reaction. D. Berthelot and H. Gaudechon observed no reaction in the light of a quartz mercury lamp. E. Warburg and G. Leithäuser definitely proved that nitric oxide is produced by the silent electrical discharge in air at ordinary temp. when the thermal equilibrium virtually corresponds with no formation of nitric oxide. Hence, said E. Warburg, the formation of nitric oxide in the arc cannot be a purely thermal process, but electrical influences—say electronic collisions—must play a part, F. Haber and co-workers argued that the primary action in both the high-tension arc and in the silent discharge is electrical. F. Haber and A. König said that the kinetic energy of the gaseous ions and of the electrons produced in the arc, moving under the potential gradient between the electrodes, is directly utilized in forming nitric oxide by collisions of the ions and electrons and with one another and with the neutral molecules. The greater the difference of potential between the electrodes, the greater will be the kinetic energy of these ions and electrons, and the greater the production of nitric oxide. In time, a state of electrical equilibrium will be attained in which an equal number of mols. of nitric oxide is formed and decomposed by the electronic and ionic impacts. While the thermal equilibrium is determined only by the mass law and temp., the electrical equilibrium is also affected by the amount of electrical energy expended per unit time, and this also determines the difference between thermal and electrical equilibria. The difference is shown by the fact that the equilibria conditions in the action of the silent discharge in the reactions : $3O_2 \rightleftharpoons 2O_3$; $2CO + O_2 \rightleftharpoons 2CO_2$; and $N_2 + 3H_2 \rightleftharpoons 2NH_3$, at ordinary temp. are the same as the thermal equilibria at higher temp. The slowness of the reverse change at ordinary temp. accounts for the fact that the electrical equilibria are preserved when the electrical stimulus is withdrawn. If the temp. is so high that the thermal equilibrium is attained very rapidly, the electrical equilibrium will be subordinated to the thermal equilibrium, and the observed conc. of nitric oxide will correspond to the purely thermal condition any excess due to the electrical stimulus will be at once decomposed, when the electrical stimulus is withdrawn. Hence, the electrical equilibrium will be dominant only when the temp. is low enough to decompose the nitric oxide very slowly. F. Haber was able to realize this condition experimentally, by passing the gases slowly under diminished press. through narrow tubes completely filled by the arc, and cooled by a water-jacket. The yields of nitric oxide were much higher than corresponded with the simple thermal equilibrium at the temp. of the arc. Hence it was argued that the use of a low temp. arc gives better results than a high temp. arc, although the cold arc has not yet been worked industrially. The reason W. Nernst and fellow-workers obtained results in agreement with purely thermal equilibria, when working with the high tension arc, is due to the rapid secondary thermal decomposition of the nitric oxide. The thermal influence got the upper hand of the electrical. F. Haber and A. König hold that in the work of W. Muthmann and H. Hofer, A. McDougall and F. H. Howles, and J. Brode, the assumed temp. were not attained, and that in these short high-tension arcs, with alternating currents, the temp. must vary enormously at every part of the arc so that it is almost meaningless to speak of an average temp., and apply the result to calculate thermodynamic equilibrium. The high results, 6·7–7·4 per cent. of nitric oxide, obtained under these conditions might well be attained at the possible temp. of 3500°, but the thermal equilibrium at such a temp. would be so mobile that it is very improbable the conc. of nitric oxide actually attained could be maintained by rapid cooling. Hence, it is more probable that the observed results represent a kind of electrical equilibrium. These conclusions were confirmed by the work of W. Holwech, W. Holwech and A. König, S. Karrer, G. W. Morden, and F. Haber, A. König, and E. Platou. G. M. Schwab and S. Loeb worked with a cold direct current discharge with an oxide cathode, and found the velocity of formation of nitric oxide with mixtures containing 20–80 per cent. of oxygen.

F. Fischer and E. Hene suggested that the apparent deviations from the mass law observed by A. Grau and F. Russ, and the high conc. of nitric oxide obtained by F. Haber and A. König with the cooled arc, are due to the activation of oxygen in the electric arc. It is assumed that the conditions in the electric arc are favourable to the formation of ozone, and that the nitrogen is oxidized by ozone. At first, with R. Escales, they thought in harmony with R. J. Strutt's observations, that the nitrogen was also activated, but since active nitrogen yields no nitric oxide in contact with oxygen, it was concluded that the nitrogen was not activated. They found that if ordinary nitrogen is allowed to mix with oxygen which has just been exposed to the spark discharge 6·5 times as much nitric oxide is formed as when ordinary oxygen is allowed to mix with the sparked nitrogen. In answer to A. König's question how any nitric oxide is produced at all if no activation of nitrogen occurs when sparked nitrogen is mixed with oxygen, they explained that the glowing nitrogen must have produced ozone when in contact with the oxygen. If a high-tension arc discharge be employed more nitric oxide is formed when air from the arc streams into oxygen than when it streams into air or nitrogen. F. Fischer and E. Hene did not think that the result can be explained by assuming that the mixing gas diffused into the arc flame because the watt-consumption in the arc remained constant in agreement with A. Grau and F. Russ' experiments. V. Ehrlich and F. Russ found that both nitric oxide and ozone are produced by the silent discharge in air at ordinary temp. The velocity of the reaction between ozone and nitrogen at ordinary temp. is too slow to test experimentally, but F. Fischer and E. Hene argued that if the formation of nitric oxide is due to the primary formation of ozone, the reaction should become perceptible at elevated temp. They found:

	20°	380°	430°	510°	700°
Nitric oxide . .	0·00	0·02	0·02	0·04	0·06 per cent.

No ozone was observed except at 20°; and no nitric oxide was formed at 700° without the discharge. They pointed out that the reaction $2O_3+N_2=2NO+2O_2+250$ Cals. is exothermal. It was therefore assumed that in the high-tension arc the oxygen is dissociated to atoms, and outside the arc, the atoms unite with oxygen mols. to form ozone. The formation of nitric oxide is assumed to be preceded by the activation of the oxygen, but whether oxygen atoms act directly on the nitrogen is not known. It is further suggested that the yields of nitric oxide might be improved by passing oxygen instead of air through the arc, and then mixing it rapidly with nitrogen. A. König objected to F. Fischer and E. Hene's conclusion that the nitrogen is not also activated, and believed that both gases are simultaneously activated. T. M. Lowry found that when air is passed through an ozonizer, or through a spark discharge, no nitrogen peroxide can be detected spectroscopically by a process sensitive to $\frac{1}{8000}$th part by vol.; but if the air be first passed through the ozonizer and then through the spark discharge, or *vice versa*, nitrogen peroxide is formed. O. Cramp and B. Hoyle also found that the yield of nitric oxide from the high-tension arc can be augmented by first ozonizing the air. T. M. Lowry also found nitrogen peroxide is formed by passing two currents of air through an ozonizer and spark discharge in parallel, and mixing the two currents. It was therefore assumed that the spark discharge produces a form of nitrogen which can be readily oxidized by ozone, but not by oxygen. The most advantageous method of oxidation is to produce the activated nitrogen in an atm. already charged with ozone; a less efficient method is to pass the air containing activated nitrogen into the ozonizer; and a still less efficient method is to mix air with activated nitrogen with ozonized air in a vessel a few feet away from the discharge apparatus. All this illustrates the instability of the activated nitrogen; a few seconds of time suffice for its reversion to a form oxidizable neither by oxygen nor by ozone. R. J. Strutt's active nitrogen did not give nitric oxide with ozone. The work of T. M. Lowry thus supports F. Haber and A. König's view that both oxygen and nitrogen are activated in the high-tension arc.

Assuming the temp. of the arc to be 2500°, F. Haber calculated the minimum expenditure of energy necessary to produce the corresponding amount of nitric oxide by the assumption that the reaction is purely thermal. This energy is the electrical equivalent of the heat absorbed in the reaction $N_2+O_2=2NO$, plus the heat required to raise the temp. of the gases to the temp. of the reaction. The mean sp. ht. of the three gases concerned in the reaction is taken to be $6{\cdot}8+0{\cdot}0006\theta$ cals. per mol, hence, $\frac{1}{2}(6{\cdot}8+0{\cdot}0006\times2500)=20{,}600$ cals. are needed per mol of nitric oxide; assuming the heat of formation of a mol of nitric oxide at 2500° is 21,600 cals.; therefore 42,200 cals. are needed for the production of 30 grms. or one mol of nitric oxide. This is eq. to nearly 0·05 kilowatt-hours per mol. In practice, one k.w.h. or one kilowatt-hour, with a 2 per cent. conversion, is needed for 30 grms. of nitric oxide. Hence, the energy efficiency of the arc process is about 5 per cent. Part of this can be utilized for heating boilers, etc. Hence, the arc process is very wasteful of energy, and can be employed economically only where cheap electrical power is available. This is possible in some of the hydroelectric plants in Norway, Switzerland, Canada, United States, etc. Since a mol of nitric oxide, by a series of spontaneous reactions, ultimately furnishes 63 grms. of nitric acid, the efficiency of the process is often expressed in terms of the quantity of nitric acid obtained from the nitric oxide per unit of energy—say in grams per kilowatt-hour, or in kilograms per kilowatt year. The high-tension arc, burning in air across horizontal electrodes, furnishes a true flame, the air-flame. This flame was studied by A. McDougall and F. H. Howles, W. Muthmann and H. Hofer, G. Brion, J. Brode, etc. The flame has three zones: (i) a luminous bluish band of light joining the electrodes. Here the current is carried across the air-gap, and, being heated directly by the current, the temp. is higher than in the other zones. Judging from the conc. of the nitric oxide in this zone, which J. Brode found to be about 8 per cent., the temp. is in the vicinity of 3700°. Surmounting the ozone is (ii) a broader bluish-green zone, and above this again is (iii) a feebly luminous brownish zone. The nitric oxide formed in the first zone here undergoes partial dissociation because higher conc. of this gas are obtained if this zone be cooled rapidly; some ozone is also decomposed in this zone. If the arc is formed in nitrogen gas, a single blue band is formed corresponding with the first zone of the air-flame; while the flame in oxygen gives zones corresponding with the first and second zones of the air-flame. Ozone was detected in this zone. Hence, the second zone in the oxygen- and air-flames, under conditions where it is absent in the nitrogen- or hydrogen-flame, is taken to prove that this is a zone of decomposing ozone. H. B. Moses obtained a sudden chilling of the gases and a correspondingly high yield by forming the arc over liquid nitrogen.

When the temp. of nitric oxide falls below 620°, it begins to oxidize, forming nitrogen peroxide: $2NO+O_2\rightleftharpoons2NO_2$, and below 140°, the reaction is complete—*vide* the dissociation of nitrogen peroxide, and nitric oxide. The nitrogen peroxide is absorbed by water giving a mixture of nitrous and nitric acids: $2NO_2+H_2O=HNO_3+HNO_2$; the nitrous acid is unstable under ordinary conditions, and decomposes: $3HNO_2=HNO_3+H_2O+2NO$; the nitric oxide is oxidized, forming more nitrogen peroxide, and thus the reaction goes on until all is converted into nitric acid: $4NO_2+O_2+2H_2O=4HNO_3$, in the presence of an excess of water. The nitric acid which results is therefore in dil. soln.—*vide* action of water and alkali-lye on nitrogen peroxide. With soln. of alkali hydroxide, at ordinary temp. and press., nitrogen peroxide forms a mixture of alkali nitrite and nitrate: $2NaOH+2NO_2=NaNO_3+NaNO_2+H_2O$. A mixture of equimolar proportions of nitric oxide and nitrogen peroxide behaves towards a soln. of alkali-lye as if it were nitrous anhydride, and produces alkali nitrite alone: $NO_2+NO+2NaOH=H_2O+2NaNO_2$. Hence, by choosing the right temp. for $2NO+O_2\rightleftharpoons2NO_2$, it is possible to prepare alkali nitrite (*q.v.*) alone from the oxidation products of nitrogen. E. D. McCollum and F. Daniels absorbed the nitrogen peroxide produced by means of silica gel.

A number of furnaces have been devised for the oxidation of nitrogen in the electric arc. There is K. Birkeland and S. Eyde's furnace [5] in use at Froguerikelm, Aukerlokken, Notodden, Svaelgfos, Lienfos, and Rjukan, in Norway—hence often alluded to as the Norwegian process—and at Soulom, Pyrenees ; J. von Kowalsky and I. Moscicky's furnace in use at Chippis in Switzerland ; O. Schönherr's furnace used at Christiansand, and Saaheim, in Norway, and also in Germany ; and H. Pauling's furnace, in use at Patsel, Innsbruck ; Gelsenkirchen, Westphalia ; Mulderstein, Saxony ; Roche de Rame, France ; Legnano, Milan ; Nitrolee, U.S.A. ; E. K. Scott's, P. A. Guye's, and J. S. Island's furnaces have not yet passed the experimental stages. Many others have been patented, but have not succeeded in making their way.

In **K. Birkeland and S. Eyde's furnace,** the arc between the electrodes is maintained by an alternating current of about 5000 volts and 50 periods per second, and is spread by a strong magnetic field into two semicircular discs of flame at right angles to the axis of the electrodes. The sheets of flame alternately rise and break with great rapidity in the upper and lower half of the reaction chamber. The impression on the eye is that of a steady circular sheet of flame about 1·8 metres in diameter. The electric flame is produced in a flat box of refractory material which does not attain a temp. of 1000° and is surrounded by an iron shell. The refractory lasts from 4 to 6 months. The walls of the refractory material, Fig. 60, are perforated with small openings through which air enters the reaction chamber, and impinges on the flame. The air was formerly forced through the furnace ; it is now aspirated into the furnace. A peripheral channel in the reaction chamber allows the products of the combustion to be carried away. The bevelled poles of the electromagnet are imbedded in the lining of the furnace ; the coils of the electromagnet are just outside the iron shell ; and the magnet is fed by a direct current. The electrodes are U-shaped copper tubes, cooled by a rapid current of water passing through them. They are replaced about every 3 weeks. The temp. of the flame is estimated to be 3000°–3500° ; and the temp. of the escaping gases is 800°–1000°. They then pass from the furnace into boilers used for steam-raising ; and are then led at about 250° to cooling chambers where the temp. is reduced to about 50°. The gases pass from the coolers to the absorption towers—usually 3 or 4. These towers are made of Norwegian granite ; they are about 23 metres high, and are filled with pieces of quartz. The gases enter at the bottom of the first tower and alternately top and bottom of succeeding towers. Dil. nitric acid trickles down the first two or three towers, and water down the last one. The acid from the first tower is the most conc. being about 30 per cent. HNO_3, and that taken from the three succeeding towers is respectively 20, 10, and 5 per cent. The acid is transferred from one tower to the preceding one of the series. The gas from the fourth tower enters a similar absorption tower through which a soln. of sodium carbonate containing 2 per cent. sodium hydroxide percolates. Sodium nitrate and nitrite are formed. The plan of the plant is illustrated by Fig. 62.

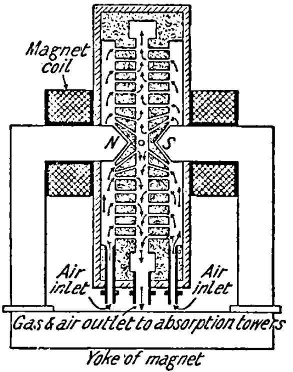

FIG. 60.—K. Birkeland and S. Eyde's Furnace (Longitudinal section showing electromagnets and reaction chamber).

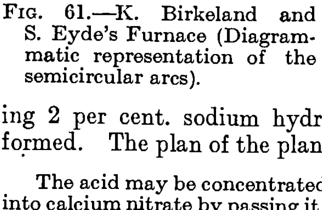

FIG. 61.—K. Birkeland and S. Eyde's Furnace (Diagrammatic representation of the semicircular arcs).

The acid may be concentrated by evaporation in special towers ; or it may be converted into calcium nitrate by passing it over limestone. The soln. of calcium nitrate is evaporated until it contains about 13 per cent. of available nitrogen when it is solidified rapidly by passage over cooled rollers. The calcium nitrate or rather basic calcium nitrate has been called *Norwegian saltpetre*, *lime-saltpetre*, and *l'azote calcaire*. The soln. of sodium nitrate and nitrate may be evaporated and sold for use in making sulphuric acid, or the nitrite may be obtained in crystals for use in dye-making. The problems connected with the absorption towers have been discussed by F. Förster and co-workers, J. A. Hall and co-workers, G. N. Lewis and A. Edgar, J. R. Partington and L. H. Parker, W. G. Schaposhnikoff, E. S. Burdick and C. L. Freed, G. Lunge and E. Berl, M Bödenstein, E. K. Rideal, G. W. Todd, M. Oswald, etc. Modifications have been devised by O. Meister and co-workers, A. A. Naville and P. A. and C. E. Guye, A. Schlösing, I. Moscicky, F. Bergius, O. Engels and F. Dürre, Det Norsk Hydroelektrisk Kuaelstofaktieselskab, etc.

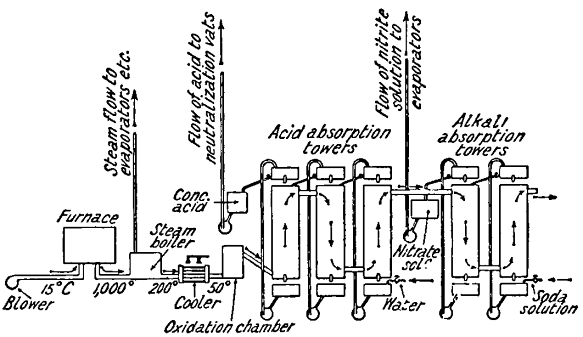

Fig. 62.—Diagrammatic Plan of Plant for the Fixation of Nitrogen by Oxidation.

In **J. von Kowalsky and I. Moscicky's furnace,** the reaction chamber is water-cooled, and the arc revolves under the influence of a powerful magnetic field, Fig. 63, with the lines of force parallel to the common axis of the electrodes. The revolving arc practically fills the working space between the electrodes. In the diagrammatic representation, Fig. 63, the air enters at *A* ; and flows past the arc *B* into the cooled chamber, *C*, and passes through *D* on to the absorption towers. The arc is maintained between the high potential electrode, *E*, and the earthed neck of the furnace *F*. As shown in the diagram, some air can enter the chamber without passing through the arc ; this is considered to be a source of weakness.

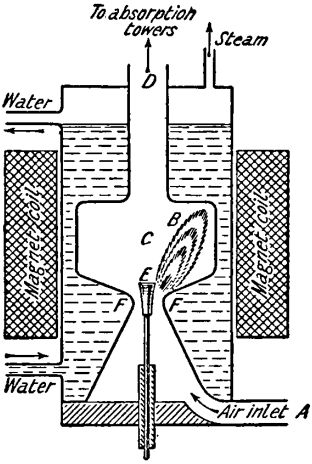

Fig. 63.—Diagrammatic Representation of J. von Kowalsky and I. Moscicky's Furnace.

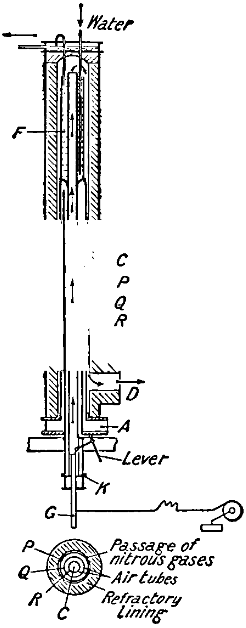

Fig. 64.—O. Schönherr's Furnace.

In **O. Schönherr's furnace,** a long slender arc is developed in the axis of an iron tube through which a current of air is forced. The arc is established by imparting a whirling motion to the air. The arc is struck by touching the iron electrode *G* against the inner tube. The air enters at *A*, and passes upwards between the steel tubes *P* and *Q*, and then downwards between *Q* and *R*. The air is thereby pre-heated before it enters the hot reaction chamber through the opening *K* arranged tangentially so as to give a whirling motion to the upward current of air in the reaction chamber *C*. The upper part of this chamber *C* is cooled by the water-jacket *F*. The reaction chamber *C* serves as one electrode, the other electrode *G* is water-cooled, and insulated from the furnace. The nitrous gases pass out of the reaction chamber *viâ* the annular space which separates the tube *P* from the refractory lining, and from *D* to the absorption towers. The process was discussed by F. Kodera and co-workers.

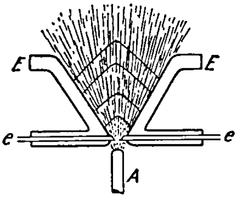

FIG. 65.—The Electrodes and Arc of H. Pauling's Furnace.

In **H. Pauling's furnace,** the arc is formed between hollow, cast-iron, or, as recommended by E. Rossi, water-cooled electrodes bent in the form of two horns *EE*, Fig. 65 ; and an arc is struck by means of the kindling blades *ee*. The air-blast from *A* forces the arc upwards and fan-wise along the inclined electrodes when it is extinguished, and a new arc follows at every half cycle of the alternating current. The arc often attains a height of three feet, the preheated air enters the reaction chamber *viâ A*, Fig. 66, and the products of combustion leave that chamber *viâ B*. One furnace with two arcs in series is placed in each leg of a three-phase current supply. There is an arrangement for momentarily supplying the special current necessary for kindling the arc.

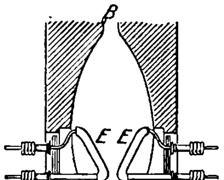

FIG. 66.—Vertical and Horizontal Sections of H. Pauling's Furnace.

In **E. K. Scott's furnace,** three horn-shaped electrodes are set at an angle of 180°, and with sides inclined towards each other at an angle of 30° from the vertical, and with intermediate refractory material, so as to form a six-sided conical space with its apex at the bottom. A blast of air is projected through the space where the electrodes converge, and bafflers are placed to force it to pass through the arc. With a 3-phase current of 60 periods, a combined arc of 360 separate flames per second is flared out by the air current. A tubular boiler placed directly above the arc cools the escaping gases from about 1000° to about 250°, and utilizes the waste-heat. In **J. S. Island's furnace,** there is a circular revolving electrode moving within a fixed annulus which forms the other electrode ; the air enters the annules, passes through the arc ; then into cooling coils, and thence to the absorption chambers.

Summaries of the patent literature or bibliographies have been made by R. H. Hosmer [6] and S. C. Stuntz. Many others have written on the subject.[7] There are also a number of brochures or books on the subject : P. Vageler, *Die Bindung des atmosphärischen Stickstoffs in Natur und Technik,* Braunschweig, 1908 ; E. Donath, *Die technische Ausnutzung des atmosphärischen Stickstoffes,* Leipzig, 1907 ; F. von Lepel, *Die Bindung des atmosphärischen Stickstoffes insbesondere durch elektrische Entladungen,* Greisswald, 1903 ; W. Schneidewind, *Die Stickstoffquellen und die Stickstoffdüngung,* Berlin, 1908 ; *Weitere Versuche über die Wirkung verschiedener Stickstoffformen aus den Jahren* 1908–1911, Berlin, 1912 ; A. König, *Ueber die Oxydation des Stickstoffes im gekühlten hochspannungsbogen bei Minderdruck,* Halle, 1908 ; K. W. Jurisch, *Salpeter und sein Ersatz,* Leipzig, 1908 ; R. Huber, *Zur Stickstofffrage,* Bern, 1908 ; G. Brion, *Luftsalpeter seine Gewinnung durch den elektrischen Flammenbogen,* Berlin, 1912 ; T. Pfeiffer, *Stickstoffsammelnde Bakterien,* Berlin, 1912 ; A. Perlick, *Die Luftstickstoff Industrie in ihrer volkswirthschaftlichen Bedeutung,* Leipzig, 1913 ; J. Knox, *Fixation of Atmospheric Nitrogen,* London, 1914 ; J. R. Partington and L. H. Scheuer, *Recherches sur la préparation de oxydes d'azote au moyen de décharges à haute tension,* Genf, 1905; B. Waeser, *Die Luftstickstoffindustrie,* Leipzig, 1922; London, 1926.

The entrapping of nitrogen during oxidations in air.—M. Laroche[8] observed that no nitric acid is formed when a mixture of nitrogen and oxygen, confined over potash-lye and mercury, is exposed to 50 atm. press. F. Kuhlmann detected no nitric acid in a mixture of oxygen and nitrogen which had been passed through a red-hot tube, alone or in presence of platinum or platinum-black, or in moist or dry manganese dioxide. H. Davy, however, obtained nitric acid when a platinum wire is heated electrically to its m.p. in a mixture of nitrogen, oxygen, and hydrogen; F. Haber and J. E. Coates, and F. Fischer and H. Marx observed the formation of nitric oxide at white-hot surfaces in air; and the Westedeutsche Thomasphosphatwerke proposed to make nitrogen peroxide by passing air and steam through a thin-walled porcelain tube at 1600°. The diffusion of the hydrogen so formed was hastened by raising the internal press. of the gases, and lowering the press. of those outside. E. Rossi observed that some nitric acid was formed when a Nernst's filament is heated in air. J. Priestley, A. B. Fourcroy, A. Séguin, L. N. Vauquelin, and H. Cavendish noted that the water, formed by the combustion of hydrogen in oxygen mingled with nitrogen, sometimes contained nitric or nitrous acid. The French chemists considered that slow combustion was the only means of preventing the development of the acid. H. Cavendish, however, showed that when the combustion was rapid, say by detonation, the water was free from acid, and that nitric acid was formed when the oxygen predominated. N. T. de Saussure said that the freedom from nitric acid in the former case is only apparent because ammonia is simultaneously formed and this neutralizes the acid. A. Wolokitin obtained practically no oxidation during the combustion of hydrogen in air at ordinary press., but at 20 atm. press., 0·3 mol of nitric oxide was formed per 100 mols of water. H. Tominaga observed that the oxyhydrogen flame is not to be regarded as a mere source of heat because the water vapour is dissociated, forming nitric oxide. By passing a mixture of hydrogen (1·8–6·0 parts) and nitrogen (one part) at press. up to 30 atm. on to an oxyhydrogen flame with a porcelain jet, approximately equal parts of ammonia and nitric oxide were formed. Ammonium nitrate is produced when a stream of hydrogen or hydrocarbon is burnt slowly in air, and the condensed water spontaneously evaporated. R. Bunsen also noticed the formation of nitrogen oxides when electrolytic gas is exploded with air, and K. Finckh measured the proportion of nitric oxide formed when different proportions of electrolytic gas and air are exploded—*vide* **1**, 3, 7; and M. Berthelot determined the amount formed when the gases are burnt at different press. in a bomb calorimeter. E. A. Grete and P. Zöller, L. I. de Nagy Ilosva, W. Hempel, J. Pintsch, H. Kolbe, and A. W. Hofmann also noted that during the combustion of hydrogen in air, a little nitrogen is entrapped so to speak, during the oxidation, and some nitric acid is formed. S. Nagihin found that nitric acid is formed in the flame of an ordinary laboratory gas burner. A similar result was obtained by H. B. Jones, R. Böttger, A. Figuier, A. von Bibra, J. D. Boeke, A. W. Hofmann, A. R. Leeds, G. Defren, C. Wurster, E. Cramer, J. Pintsch, and L. T. Wright, during the combustion of coal gas in air; in the combustion of alcohol, wax, coal-gas, and other organic compounds in air; F. Haber and J. E. Coates, in the combustion of carbon monoxide, ethylene, and hydrogen; L. T. Wright, in the combustion of ammonia in air; and M. Berthelot, and F. C. A. Stohmann, during the combustion of nitrogenous substances.

In 1878, J. P. Rickman described an apparatus for the oxidation of nitrogen by heating a mixture of coke and a fixed base in contact with air. L. Hackspill and A. Conder observed nitric acid was formed in the manufacture of carbon dioxide during the combustion of coke, containing nitrogen; and F. Häusser, and W. A. Bone and co-workers, during the combustion of carbon monoxide under high press. in the presence of nitrogen. H. A. Humphrey devised an apparatus for exploding under press. an explosive mixture of gases containing oxygen and nitrogen under conditions to give the best yields of nitric oxide. The subject was also discussed by F. Haüsser, and C. J. Goodwin. O. Brunier entrapped nitrogen as oxide by burning oil or gas fuel under water or lime-water. M. Berthelot, and W. Hempel observed the formation of nitric acid during the combustion of carbon, or sulphur in oxygen with 8 per cent. of nitrogen contained in a calorimeter bomb, but was formed in the combustion of iron or zinc; but L. I. de Nagy Ilosva obtained nitrous oxide by using iron at 190°–250°. H. Kämmerer, and A. Müntz and E. Aubin observed nitric acid was formed during the combustion of magnesium in air; and J. F. Heller, A. R. Leeds, C. F. Schönbein, and M. Zabelin observed its formation during the slow oxidation of phosphorus; and M. Berthelot, when ether is exposed to light and air. F. Häusser devised a process for making nitric acid by detonating ordinary coal gas, or coke-oven gas mixed with an excess of air, or air enriched with oxygen, in a bomb under press.—say 5 atm. The gases are cooled rapidly after the explosion, and the 0·3–0·6 per cent. of nitric oxide formed recovered from the products by a train of absorption towers. The apparatus is continuous, fifteen explosions being produced per minute. Modifications were suggested by J. Görlinger, H. Nöh, and H. Woll. O. Dobbelstein studied the costs when coke-oven gas is employed. O. Bender proposed to burn the natural gas of Transylvania under press. in modified Bunsen's burners, and to recover the nitric oxide from the products of combustion. F. Gerhardt observed the production of nitric oxide in the combustion of the gases in gas-engines.

W. T. David and co-workers showed that ultra-red radiation hastens the combustion of mixtures of carbon monoxide or ethane and air or oxygen provided that the radiation is of a kind which is absorbed by the combustible gas, or nitrogen is present as a constituent of the inflammable mixture. The sympathetic oxidation of nitrogen which occurs indicates that nitrogen plays some part in the process of combustion. W. T. David and co-workers assume that during the combustion there is some kind of temporary association or interplay between the nitrogen molecules and those of the combustible gas which tends to retard combustion; and that the association is to some extent inhibited when the molecules of the combustible gas acquire vibratory energy by the absorption of the ultra-red radiation, with a consequent increase in the rate of combustion.

§ 32. Nitrogen Oxides—Nitrous Oxide or Hyponitrous Oxide

There are five oxides of nitrogen. Three of these by composition can be regarded as anhydrides of acids. Thus:

Nitrous oxide . . .	N_2O	(Hyponitrous acid . . .	$H_2N_2O_2$)
Nitric oxide	NO	(Nitrohydroxylaminic acid .	$H_2N_2O_3$)
Nitrogen trioxide . . .	N_2O_3	Nitrous acid	HNO_2
Nitrogen peroxide or tetroxide	$NO_2(N_2O_4)$	Nitric acid	HNO_3
Nitrogen pentoxide . .	N_2O_5		

N_2O is sometimes called *nitrogen monoxide;* NO, *nitrogen dioxide;* N_2O_3, *nitrogen trioxide;* N_2O_4, *nitrogen tetroxide;* and N_2O_5, *nitrogen pentoxide.* If so, NO_2, the allotropic form of N_2O_4, cannot be called nitrogen dioxide. It is doubtful if *hyponitrous acid* is the acid of nitrous oxide regarded as an anhydride; and still more doubtful if *nitrohydroxylaminic acid—vide supra—*is the acid of nitric oxide regarded as an anhydride. So far as mere composition goes, however, a mol of these oxides plus a mol of water furnishes the acids in question. Hyponitrous acid is an isomer of *nitramide*, or *nitroxyl amide.* The individuality of higher oxides or acids is not so well established.

P. Hautefeuille and J. Chappius[1] found that the silent electrical discharge in a mixture of oxygen and nitrogen at a low press. does not form ozone: but M. Berthelot, and P. Hautefeuille and J. Chappius observed that a spark or powerful silent discharge produces *une acide pernitrique*, which is decomposed into nitrous or nitric acid by the attendant rise of temp. Consequently, the ozone produced by the action of the electric discharge on dry air is mixed with pernitric acid. The formation of the latter compound is limited, like that of ozone, and the maximum corresponding with a given temp. may be determined from the diminution of press. Moreover, when the maximum is reached, the pernitric acid undergoes periodic retrogradation and re-formation as already observed in the case of ozone. This decomposition of the pernitric acid into oxygen and nitric acid also causes the decomposition of the admixed ozone, even at press. above 100 mm., although ozone unmixed with pernitric acid does not undergo retrogradation at these press. This result is probably due to the development of heat accompanying the decomposition of the pernitric acid. At ordinary press. in presence of certain proportions of nitric acid, the ozone and pernitric acid are not re-formed, but under low press. they are again produced. The amount of pernitric acid formed depends more on the temp. than on the relative proportions of oxygen and nitrogen; and to obtain a good yield the operation should be conducted at a low temp. The maximum quantity produced at 15° under a press. of 600 mm. is about 30 per cent. by weight. The formation and decomposition of the pernitric acid may be traced with the aid of the spectroscope. The absorption spectrum observed by J. Chappius is characterized by fine lines in the red, orange, and green; the most characteristic ones correspond with wave-lengths 6680–6650, and 6280–6250. Water or a trace of moisture immediately causes the spectrum to disappear, and the substance is therefore an anhydrous compound capable of forming an acid. The mixture of ozone and the new substance is changed by heat, yielding nitric acid. At ordinary temp. the change is slow, and a period of from 24 to 48 hrs. occurs after the disappearance of the dark lines of the new substance, before those of the nitric acid make their appearance. On cooling a mixture of oxygen, nitrogen, and ozone charged with the vapours of pernitric acid to —23°, a small quantity of a highly volatile crystalline powder is condensed, but cannot be isolated. An indirect analysis gave for the ultimate composition: NO_3, or N_2O_6, which L. Spiegel represented by the graphic formula $NO_2.O.O.NO_2$—**nitrogen hexoxide.** E. Warburg and G. Leithäuser obtained an analogous product by the action on ozone of nitrous gases. F. Raschig *assumed* that an unstable mixture of nitrogen hexoxide and nitrogen heptoxide is formed when nitric oxide acts on a large excess of oxygen. This could not be isolated. According to D. Helbig, when a series of electrical discharges is sent through liquid air, a flocculent, unstable, greenish substance is formed which decomposes in air at a low temp. giving off reddish vapours. The decomposition is sometimes explosive. The composition corresponds with that of nitrogen hexoxide. When suspended in the excess of liquid air, nitrogen hexoxide bears a strong resemblance to precipitated chromic hydroxide, but when the air has been removed by evaporation under reduced press. it forms a slightly blue, amorphous powder. It melts at —111°, and at the same time assumes a deep azure colour, which persists after the liquid has been resolidified by immersion in liquid air. The fused oxide decomposes, yielding nitric oxide, which is also evolved when the liquid is placed in a vacuum. F. Raschig obtained green flocks of what he considered to be the same compound by passing dry nitric oxide into liquid oxygen, and allowing the excess of oxygen to evaporate. E. Müller showed that neither the composition nor the m.p. is constant, and inferred that the green substance is a mixture. The colour may be exactly imitated by dipping a test-tube containing liquid air in liquid nitrogen trioxide, and, after a frozen layer has been formed, in liquid nitrogen tetroxide. The two layers of blue and yellow give a green which is exactly like that of the supposed hexoxide. According to R. L. Hasche, the green solid obtained by bubbling nitric oxide through liquid oxygen, or by the action of air on solid nitric oxide at the temp. of liquid oxygen, is a **nitrosonitrogen trioxide,** $(N_3O_4)_n$. It decomposed above the b.p. of oxygen to the blue oxide, N_2O_3, of D. Helbig. F. Raschig's formula is considered not to be correct. Assuming, because of its instability and its instantaneous formation, that the green oxide is a peroxide of polymerized nitric oxide, its formation may be explained as follows: $O.O+2(NO.NO.N:O)\rightarrow O:N.NO.O.O.NO.NO.N:O$. The phenomena observed in the oxidation of nitric oxide may be explained by the assumption of similar intermediate compounds, *viz.*, at higher temp., O : N.NO.O.O.NO.N : O, formed by the oxidation of $(NO)_2$, and, in the gaseous state, O : N.O.O.N : O, formed by the oxidation of NO.

By treating soln. of the alkali nitrates with sodium dioxide, E. Pinerua-Alvarez claimed to have made alkali salts of true **pernitric acid,** HNO_4. Thus, 160 grms. of sodium dioxide were gradually added to a well-cooled soln. of 100 grms. of potassium nitrate in 200 c.c. of water, and 1200 grms. of alcohol. An amorphous precipitate of **potassium pernitrate,** KNO_4, was obtained on adding 1200 grms. of alcohol, and rapidly filtering: $KNO_3+Na_2O_2+H_2O=KNO_4+2HaOH$. More pernitrate was removed by evaporating the filtrate. The salt is decomposed by water or acids producing hydrogen dioxide or oxygen. F. Raschig reported pernitric acid to be formed by the interaction of nitrogen peroxide and hydrogen dioxide. J. Schmidlin and P. Massini found that the product did not oxidize manganous salts, and they therefore suggested that it is not a true per-acid, but rather *nitrous hydroperoxide.* I. Trifonoff obtained pernitric acid by the action of hydrogen dioxide on an acidified soln. of a nitrite. Above 70°, the product decomposes rapidly; it liberates bromine from potassium bromide. The formula is represented by $NO_2.O.O.NO_2$ plus nH_2O; and the reaction by which it is formed, by $2HNO_2+3H_2O_2+(n-1)H_2O=N_2O_6 \cdot nH_2O+3H_2O$. Aniline, benzene, toluene, xylene, and the aliphatic hydrocarbons are coloured yellow by pernitric acid. F. Pollak established the formation of pernitric acid from nitric acid and hydrogen dioxide in the presence of potassium bromide. At 15°, the initial velocity of bromine separation is proportional to the first power of the nitric acid conc. and the potassium bromide conc. The exponent for the hydrogen dioxide, however, is approximately 0·80. Different reactions are found to predominate if the same relative quantities of reactants are present, but the total conc. is different. The influence of light is also a disturbing factor. *Vide* silver peroxynitrate, **3.** 22, 23, for the possible formation of a **silver pernitrate** during the electrolysis of an aq. soln. of silver nitrate. E. Mulder and J. Heringa suggested that silver peroxynitrate, $3Ag_2O_2 \cdot AgNO_3$ (*q.v.*), is possibly a salt of *hypernitric acid,* HNO_5, or $HO \cdot NO_4$, *i.e.* of the anhydride, *nitrogen enneaoxide,* N_2O_9:

$$\begin{matrix}O_2\\O_2\end{matrix}\!\gg N-OH$$

Hypernitric acid.

$$\begin{matrix}O_2\\O_2\end{matrix}\!\gg N-O-N\ll\!\begin{matrix}O_2\\O_2\end{matrix}$$

Nitrogen enneaoxide.

E. P. Alvarez[2] found that the pernitrates react with soln. of lead acetate (white precipitate), silver nitrate (white precipitate), mercurous nitrate (white precipitate with rapid decomposition), mercuric chloride (red precipitate), copper sulphate (blue precipitate), zinc and cadmium sulphates (white precipitate), bismuth nitrate (white precipitate), gold chloride (slight effervescence and escape of oxygen), manganous chloride (pink precipitate), nickelous chloride or sulphate (greenish-white precipitate), cobaltous nitrate and chloride (pink precipitate), ferrous sulphate (green or bluish-green precipitate), ferric chloride (red ferric hydroxide), and alkaline earth chlorides (white precipitates). The precipitates are all per-salts of the bases in question.

In 1772, J. Priestley[3] compared the action of fixed air (carbon dioxide) and of nitrous air (nitric oxide) on moist iron, and observed no sensible change with the former gas, but the latter gas was "transformed into a species of air in which a candle burned quite naturally, and freely, and which is yet in the highest degree noxious to animals insomuch that they die the moment they are put into it; whereas, in general, animals live with very little sensible inconvenience in air in which candles have burned out." He later showed that the candle burns in the new gas with an enlarged flame; and that whereas if liver of sulphur be substituted for iron, the conversion of the nitric oxide to the new gas is shortened from 6 to 8 weeks to 24 hrs.—especially if the liver of sulphur be kept warm. He also found that the same gas is formed when zinc or tin is dissolved in spirit of nitre (nitric acid). He called the new gas *dephlogisticated nitrous air ;* it is now known as **nitrous oxide,** N_2O. In 1793, J. R. Deiman and co-workers prepared this gas by heating ammonium nitrate, and showed that it is a lower oxide of nitrogen than nitric oxide. In 1800, H. Davy made an extensive investigation on the gas and discovered its intoxicating qualities, from which it obtained its name *laughing gas.*

The preparation of nitrous oxide.—Nitrous oxide is not easily formed by direct union of oxygen and nitrogen. M. Berthelot and H. Guadechon obtained none under the influence of ultra-violet light. E. Warburg and G. Leithäuser found that when a mixture of oxygen and nitrogen is passed through an ozonizing tube, nitrous oxide, and nitrogen pentoxide are formed; if the mixed gas is sparked between platinum electrodes, nitrous oxide and nitrogen peroxide are formed; and when exposed to the alternating arc of high tension, nitric oxide and nitrogen peroxide are formed. According to D. L. Chapman and co-workers, nitrous oxide is slowly formed when an electric discharge is passed through nitrogen at a low press. in a quartz tube into the walls of which oxygen has previously been driven by means of the discharge. C. Matignon argued from thermodynamical considerations that the production of nitrous oxide ought to be possible by the direct union of oxygen and nitrogen at 3000° and 3000 atm. Unless the gas was rapidly removed from the hot zone and cooled, the yield would be only 0·1 per cent. According to R. Pictet, and K. A. Söderman, the nitrogen-oxygen flame produced electrically or by other means shows spectroscopically that nitrous oxide is present in some parts ; and by rapid cooling, it is possible to obtain a 25 per cent. yield—*vide supra,* the fixation of nitrogen.

Nitrous oxide is commonly made by the process of J. R. Deiman and co-workers, *viz.*, by heating anhydrous, neutral ammonium nitrate to 170°–260°. The gas can be collected over water, brine, or mercury. The ammonium nitrate used should be free from chlorine. According to E. Thilo, most of the commercial ammonium nitrate is not sufficiently purified for use in making the gas. Any nitric oxide which might be formed can be removed by passing the gas through a soln. of ferrous sulphate. P. Cazeneuve said that the gas may retain an irritating odour even after its passage through a soln. of ferrous sulphate, and of sodium hydroxide. He attributed this to the presence of a little hyponitrous acid, and it was removed by shaking the gas several times with a soln. of ferrous sulphate, or allowing it to stand 24 hrs. in a gas-holder. P. Villard said that nitrous oxide of a very high degree of purity is obtained by converting the gas first into the hydrate, and then allowing the hydrate to decompose. P. Cazeneuve explained the explosion which sometimes take place in the preparation of the gas by the fact that the decomposition of ammonium nitrate is an exothermic reaction, and that the large quantity of heat thus liberated added to that directly applied, is capable of causing the sudden decomposition of the whole mass of the salt. The process is often slow in beginning on account of the contained moisture, and hence the operator is apt to apply undue heat at first. Therefore, the salt should previously be dried in a capsule at a temp. below 200°, and the retort should be heated slowly until the disengagement of gas begins, when only a very gentle heat will be required, and the operation should not be pushed too far towards the end. V. H. Veley has studied the way the salt decomposes when heated—*vide* **2**. 20, 38. According to A. P. Lidoff, the gas as usually prepared contains appreciable quantities of nitrogen, nitric oxide, and other impurities, and he recommended the following process :

> A tube of difficultly fusible glass, sealed at one end, is filled with a mixture of 3 parts of dry sea-sand and 2 parts of ammonium nitrate dried at 105°, which is kept in position by an asbestos plug ; the end of the tube is closed by a cork through which passes a delivery tube with a tap. A small aluminium box, fitted with a thermometer and serving as an air-bath, is arranged to slide along the tube. The best temp. to employ is 260°–285°, and the back end of the tube is first heated ; when all the air has been expelled from the tube, the gas is passed, first through aqueous ferrous sulphate or alkaline sodium sulphide soln.,

and then through an emulsion of dry ferrous sulphate in conc. sulphuric acid ; it is then pure and dry.

V. H. Veley found that the reaction is accelerated by inert substances like ground-glass, pumice, silica, barium sulphate, graphite. P. Grouvelle used a mixture of potassium nitrate and ammonium chloride (3 : 1) in place of ammonium nitrate. According to A. M. Pleischl, the product is a mixture of chlorine, nitrogen, and nitric oxide with a little nitrous oxide, but E. Soubeiran said no nitrous oxide is thus produced. W. Smith and W. Elmore patented a mixture of dried commercial sodium nitrate, potassium nitrate, and ammonium sulphate (17 : 20 : 13–14), which yields nitrous oxide when heated to about 230° for the greater part of the reaction, and finishing at 300°. The apparatus should be arranged so that the condensed water does not drip back into the retort. The gas should be washed in a dil. acid, and dil. alkali-lye. W. Smith found that in this reaction, as the temp. rises ammonia is first evolved : $(NH_4)_2SO_4=NH_3+(NH_4)HSO_4$, the ammonium hydrosulphate begins to react with the sodium nitrate—possibly forming NH_4NaSO_4 and HNO_3 ; but this change proceeds slowly, and the ammonia reacts with the liberated nitric acid, forming ammonium nitrate. At about 240°, the ammonium sodium sulphate reacts with sodium nitrate, forming sodium sulphate and ammonium nitrate which then decomposes : $NH_4NO_3=N_2O+2H_2O$. If the temp. falls below the point of evolution of nitrous oxide—about 240°—the ammonium nitrate formed cannot decompose into nitrous oxide. K. A. Hofmann and G. Buhk said that nitrous oxide mixed with very little nitrogen and nitric oxide can be conveniently made at ordinary temp. by the action on copper of 14 grms. of sodium nitrite, 22 grms. of ammonium chloride, sulphate, or hydrocarbonate in 200 c.c. of water. The 1025 c.c. of gas contained 845 c.c. of nitrous oxide, 81 c.c. nitric oxide, and 99 c.c. of nitrogen. The reaction is due in the first place to the reduction by the copper of free nitrous acid formed by hydrolysis of ammonium nitrite (produced by double decomposition of the sodium nitrite and ammonium salt), $2HNO_2+Cu=2NO+Cu(OH)_2$. The cupric hydroxide dissolves in the ammonia (a blue colour appears on the surface of the copper), and is reduced by copper to the cuprous form. The cuprous oxide then reduces the nitric oxide further to nitrous oxide, $2NO+Cu_2O=N_2O+CuO$. The free nitrogen must be formed by the normal decomposition of ammonium nitrite into nitrogen and water. Magnesium nitrite behaves in a similar manner with copper, but, since it is much less hydrolyzed than ammonium nitrite, the reaction proceeds at only about one-sixtieth of the rate.

In the original process employed by J. Priestley for preparing this gas, nitric oxide was reduced by means of iron or liver of sulphur ; F. Kuhlmann reduced that gas with hydrogen sulphide, dry or moist liver of sulphur, iron- or zinc-filings, moist iron sulphide, or sulphur dioxide—gas or aq. soln. ; J. L. Gay Lussac, a soln. of stannous chloride, or ammonia ; and G. Lechartier, an alkaline soln. of pyrogallol. Nitrous oxide is formed in the reduction of nitric oxide by sulphur dioxide, for if the mixed gases (2 : 1) be allowed to stand over water for some hours, J. Pelouze observed the formation of nitrous oxide. J. Gay found that a soln. of nitric oxide in ferrous sulphate is readily reduced to nitrous oxide by, say, ferrous oxide. J. Donath obtained the gas by the action of an alkaline soln. of a copper salt on hydroxylamine chloride. E. Cardoso and E. Arni, by the action of a sat. aq. soln. of sodium nitrite on hydroxylamine in vacuo, and subsequently fractionating the washed solid ; and G. Oesterheld, by the electrolytic oxidation of an alkaline soln. of hydroxylamine at a platinum anode. It is here assumed that hyponitrous acid is first formed, $2NH_2OH+O_2=2H_2O+H_2N_2O_2$; and that the acid breaks down into nitrous oxide and water : $H_2N_2O_2=N_2O+H_2O$. The nitrogen simultaneously produced cannot be derived from ammonium nitrite because no ammonia is present, and because there can be no oxidation of hydroxylamine to nitrous acid at the low anode potential which was maintained. The simplest explanation is that the nitrogen is due to the reaction between hydroxylamine and nitroxyl which is the first oxidation product, $O:NH+NH_2OH=N_2+2H_2O$. A. Angeli has observed the same reaction when nitroxyl splits off from benzene sulphohydroxamic acid in presence of hydroxylamine. While two mols. of nitroxyl may combine to form hyponitrous acid or nitrous oxide and water, yet there is a quantitative evolution of nitrogen so long as there is a sufficient excess of hydroxylamine. It is also possible that nitrogen may be formed simultaneously with nitrous oxide by a different decomposition of hyponitrous acid, indicated by M. Berthelot and J. Ogier, A. Hantzsch and L. Kaufmann, and P. C. Ray and A. C. Ganguli, perhaps $5H_2N_2O_2=4H_2O+2HNO_3+4N_2$; A. Thum, by the decomposition of a soln. of hyponitrous acid. M. Coblens and J. K. Bernstein found nitrous oxide but not ammonia is formed when silver hyponitrite is added to an acid soln. of titanous chloride. E. Frémy found that a soln. of nitrous acid or a nitrite is reduced to nitrous oxide by warm sulphurous acid; W. Zorn, by sodium amalgam, or stannous chloride; O. von Dumreicher, by ferrous hydroxide; and V. Meyer, and P. A. Guye and S. Bogdan, by hydroxylamine sulphate in aq. soln.—conc. soln. require heating, dil. soln. want boiling. J. Priestley reduced nitric acid to nitrous oxide by zinc or tin. N. A. E. Millon used nitric acid of sp. gr. 1·217 with zinc, tin, or copper at —10°. T. von Grotthus, and A. M. Pleischl said the gas by the zinc-reduction process is fairly pure. H. Bassett recommended a mixture of sulphuric acid (1 vol.), nitric acid (2 vols.), and water (3 vols.), and found nitrous oxide is given off in the cold when tin is used. H. Schiff used the proportions 1 : 1 : 9–10 respectively with zinc. J. J. Acworth found that in the reaction between copper and nitric acid, the resistance of much cupric nitrate favours the production of nitrous oxide. F. Mareck also reduced nitric acid with zinc. E. Frémy reduced nitric acid with sulphur dioxide; and J. L. Gay Lussac reduced aqua regia by stannous chloride. A soln. of stannous chloride in hydrochloric acid and some crystals of potassium nitrate, heated on a water-bath, gave off nitrous oxide gas. According to G. Campari, on boiling a mixture of 5 parts of stannous chloride, 10 parts of hydrochloric acid, sp. gr. 1·21, and 0·9 part of nitric acid, sp. gr. 1·38, the evolution of nitrous oxide commences, and continues to be evolved quite regularly and in a pure state. These proportions of the ingredients should be adhered to, as otherwise the gas is evolved irregularly, and even with violent explosions. A. Quartaroli reduced nitrates with formic acid: $2KNO_3+6H.COOH=N_2O+4CO_2+5H_2O+2HCOOK$.

T. Schlösing found that some nitrous oxide is formed during the lactic fermentations of organic substances in a soln. containing nitrates; and M. E. Wollny, B. Tacke, M. W. Beyerinck and D. C. J. Minkman, and S. Suzuki observed the formation of nitrous oxide during the nitrification of organic matter by bacteria.

The physical properties of nitrous oxide.—Nitrous oxide at ordinary temp. is a colourless gas, with a faint smell and sweet taste; it also forms a colourless liquid, and a colourless solid, which, according to H. E. Behnken,[4] crystallizes in the cubic system. J. de Smedt and W. H. Keesom found the **X-radiogram** of the crystals gave a space-lattice having a unit cube with side 5·72 A.; there are four mols. in the unit cube; and the distance between two neighbouring oxygen and nitrogen atoms is 1·15 A. The early determinations of the **relative density**—1·3629 by C. L. Berthollet, and 1·614 by J. Dalton—are far from the mark. A. Leduc first gave 1·52951, and later 1·5301 with an accuracy of 0·01 per cent.; Lord Rayleigh gave 1·52951, and later 1·5297. O. von Dumreicher said that the gas has a normal density at 100°. The literature was reviewed by M. S. Blanchard and S. F. Pickering. W. G. Shilling gave for the density of the gas at 0°, 0·00197. T. Wills gave 0·9004 for the specific gravity of the liquid; and L. P. Cailletet and E. Mathias found the sp. gr., D_l, to be:

	—20·6°	—11·6°	—5·5°	—2·2°	6·6°	11·7°	19·8°	23·7°
Sp.gr., D_l . .	1·002	0·952	0·930	0·912	0·849	0·810	0·758	0·698

or, the sp. gr. of the liquid at $\theta°$ between —20·6° and +23·7° is $D_l=0{\cdot}342+0{\cdot}00166\theta+0{\cdot}0922\sqrt{36{\cdot}4-\theta}$, and for the sp. gr. of the gas, D_g, they gave:

	—28·0°	—23·5°	—12·2°	—1·5°	9·2°	20·7°	28·9°	33·9°
Sp.gr., D_g	0·0378	0·0413	0·0566	0·0785	0·1066	0·1532	0·2023	0·2650

or at $\theta°$, between $-28·0°$ and $+33·9°$, $D_\theta=0·5099-0·00361\theta-0·0714\sqrt{36·4-\theta}$. J. de Smedt and W. H. Keesom estimated the sp. gr. of the solid to be 1·55. The sp. gr. of the liquid at the m.p. is 1·299. The sp. gr. at the b.p., —89·4°, was found by L. Grunmach to be 1·2257; and P. Villard gave for the sp. gr. at the critical temp., 38·8°, 0·454 for liquid and vapour. E. d'Andréeff, and P. Villard made observations on the sp. gr. of the liquid or gas; the former gave $D_l=0·9368-0·0039\theta$. L. Meyer gave 26·7 for the mol. vol. of the liquid; and R. Lorenz and W. Herz also studied this subject. For the **weight of a litre** of the gas under standard conditions, J. J. Colin gave 1·9752 grms.; and J. Dalton, 1·614. A. Leduc, and P. A. Guye and A. Pintza, first gave 1·97788 grms., and later 1·9774 grms. J. S. Stas found the molecular weight to be 43·98, hydrogen unity. A. Naumann gave for the **molecular volume,** 4·49 (hydrogen unity). R. Lorenz and W. Herz, and G. le Bas studied the mol. vol. C. E. Guye and R. Rudy, and E. Rabinowitsch gave 36 for the mol. vol. A. Naumann found the **molecular diameter** to be 2·72 (hydrogen unity); and the mol. radius, 1·65 (hydrogen unity). E. Dorn calculated the diameter to be $1·8\times10^{-7}$ cm.; H. Sirk, $3·1\times10^{-8}$ to $4·0\times10^{-8}$ cm.; J. H. Jeans, $4·6\times10^{-8}$ cm.; J. P. Kuenen, $3·1\times10^{-8}$ cm.; S. Mokruschin, $5·8\times10^{-8}$ cm.; P. Walden, $2·9\times10^{-8}$ cm.; and A. von Obermayer, $0·32\times10^{-7}$ cm. C. J. Smith calculated the mean collision area to be $0·834\times10^{-15}$ sq. cm. For the **molecular velocity,** A. von Obermayer gave 36,250 cms. per sec. at 0°, and for the **mean free path,** 387×10^{-8} cm. J. E. Mills has discussed the inter-**molecular attraction**; M. Trautz and O. Emert, F. Braun, A. Leduc, and P. Sacerdote discussed the application of the partial press. law to mixtures of nitrous oxide with carbon dioxide, etc. R. Gans, and E. Brüche discussed the structure of the molecule of the gas.

The **viscosity** of nitrous oxide gas was found by O. E. Meyer [5] to be 0·000168; O. E. Meyer and F. Springmühl gave 0·000160; C. J. Smith, 0·0001366 at 0°, 0·0001441 at 15°, and 0·0001845 at 100°; and A. Wüllner, 0·0001353 at 0°, and 0·0001815 at 100°. T. Graham's results, 0·0001408 at 0° and 0·0001600 at 20°, were too high. A. von Obermayer gave $0·0_31249$ at —21·5°, $0·0_31606$ at 53·6°, and $0·0_31829$ at 100·3°; W. G. Shilling, $0·0_31366$ at 0°; and H. Vogel, $0·0_31362$ at 0°. W. J. Fisher obtained

	25°	141·6°	183·1°	224·4°	289·9°	413·6°
$\eta\times10^7$ . .	1498	1831	2161	2348	2610	3073

A. von Obermayer represented his results at $\theta°$ between —21·5° and 100·3° by $\eta=\eta_0(1+0·003719\theta)^{0·929}$, where $\eta_0=0·0_316586$; W. J. Fisher employed $\eta=\eta_0(0·0_41707T^{\frac{1}{2}})/(1+314T^{-1})$. J. H. Jeans gave $\eta=\eta_0(T/273)^{0·93}$. Y. Ishida gave 0·795 for the ratio of the viscosities of nitrous oxide and air. W. G. Shilling gave 286 for Sutherland's constant. F. Schuster calculated 2233 atm. for the **internal pressure.** L. L. Grunmach gave for the **surface tension,** σ, of liquid nitrous oxide, 1·74 dynes per cm. at 19·8°; 2·50, at 14·4°; 9·92, at —24°; and 26·32, at the b.p., —89·3°; and for the **specific cohesion,** $A^2=0·582$ sq. mm. at 19·8°; 0·759, at 14·4°; 2·510, at —24·0°; and 4·296, at the b.p. —89·3°. For the mol. **surface energy,** $\sigma v=2·27(43·52-\theta)$, where v is the sp. vol.; if M be the mol. wt., and D the sp. gr., $M=D\{2·27(43·52-\theta)/\sigma\}^{\frac{3}{2}}$. J. Verschaffelt represented his results between 19·8° and —24°, by $\sigma=A(1-m)^{1·333}$, where $\log A=1·945$, and m denotes the reduced temp. L. L. Grunmach's results agreed with the assumption that the mol. wt. of the liquid is the same as that of the gas. A. von Obermayer [6] gave for the **diffusion** coeff. of carbon dioxide into nitrous oxide at 0°, 0·148, and J. Loschmidt, 0·098; and for hydrogen into nitrous oxide, A. von Obermayer gave 0·535. G. Hüfner measured the rate of diffusion of the gas in water and found the coeff. to be 1·35 at 16·2°; while A. Hagenbach obtained 0·63 at 14°. H. A. Daynes measured the diffusion through rubber. T. L. Ibbs and L. Underwood studied the thermal diffusion of nitrous oxide and carbon dioxide. For the velocity of sound in nitrous oxide at 0°, A. Wüllner gave 260 metres per second; G. Schweikert, 256; and W. Heuse, 257 metres per second.

A. Kundt, E. J. Irons, and C. Bender made some observations on this subject. W. G. Shilling gave at room temp., 264·6 metres per second; at 100°, 299·0; at 200°, 334·3; at 300°, 365·4; at 400°, 393·9; at 500°, 420·3; and at 600°, 446·9. N. de Kolossowsky studied the relation between the velocity of sound, and the velocity of translation of the molecules.

According to Lord Rayleigh,[7] the ratio of the **compressibility,** pv, at half an atm. to that at one atm. press. is 1·00066; and later at 11°, he obtained 1·00327. T. Bateucas gave 0·0000978 for the compressibility at 0°; and 1·00739 for the divergence from Avogadros' rule, $1+\lambda$. Observations on the **vapour pressure** of nitrous oxide were made by M. Faraday, K. Olschewsky, W. J. Janssen, J. P. Kuenen, etc. The values for the liquid by P. Villard were 30·75 atm. at 0°, and 49·4 atm. at 20°; L. P. Cailletet gave 5·05 atm. at —60°; and 13·19 atm. at —34°. The following data for the vap. press., p atm., are by G. A. Burrell and I. W. Robertson—the values at 0°, 20°, and 40° are by H. V. Regnault:

	Solid.					Liquid.				
	−144·1°	−131·3°	−117·2°	−99·5°	−90·6°	−90·1°	−88·7°	0°	20°	40°
p .	0·00158	0·0092	0·0658	0·3948	0·8686	0·9212	1	36·08	55·30	83·37

H. V. Regnault represented his results at θ°, between —40° and 35°, by $\log p = 9{\cdot}2420206 - 5{\cdot}056207\alpha^{\theta+26}$, where $\log \alpha = 9{\cdot}9991451 - 10$; C. Antoine, $\log p = 9{\cdot}4574\{1{\cdot}46927 - 1000/(\theta+1000)\}$; and G. A. Burrell and I. W. Robertson, $\log p = -1096{\cdot}7T^{-1} + 17{\cdot}5 \log T + 0{\cdot}0005T + 4{\cdot}866$, or $\log_{10} p = -1232{\cdot}2T^{-1} + 9{\cdot}579$. J. P. Kuenen studied the vap. press. of mixtures of liquid ethane and nitrous oxide. W. Nernst gave 3·3 for the **chemical constant,** and W. Herz discussed this subject.

P. von Jolly found the coeff. of **thermal expansion** to be 0·003706. C. A. Würtz gave 0·00428 between —5° and 5°; and being unity at 0°, was found to be 1·0455 at 10°, and 1·1202 at 20°. F. Guye and L. Friedrich gave for the constants in J. H. van der Waals' **equation of state** $(p+av^{-2})(v-b)=RT$, $a=0{\cdot}00723$ (or 0·00750), and $b=0{\cdot}00189$ (or 0·00195) if taken in terms of the initial vol.; $a=3{\cdot}62\times10^6$ (or $3{\cdot}72\times10^6$), and $b=42{\cdot}3$ (or 43·4) if in mols; and $a=18{\cdot}7$ (or 192), and $b=0{\cdot}961$ (or 0·987) if in grams. W. J. Walker also discussed the equation of state.

G. Wiedemann[8] first measured the **thermal conductivity** of nitrous oxide. A. Wüllner found the constant to be $0{\cdot}0_4350$ at 0°, and $0{\cdot}0_4506$ at 100°; J. Stefan gave $0{\cdot}0_4372$ at about 10°; S. Weber, $0{\cdot}0_4353$; A. Winkelmann, $0{\cdot}0_4350$ at 0°, and $0{\cdot}0_4506$ at 100°; W. G. Shilling, $0{\cdot}0_4351$; and A. Eucken, $0{\cdot}0_43515$ at 0°, and $0{\cdot}0_42710$ at —71·8°.

F. Delaroche and J. E. Bérard[9] found the **specific heat** of nitrous oxide at constant press. to be 0·2369 between 15° and 100°; H. V. Regnault, 0·226 between 16° and 207°; and E. Wiedemann gave 0·1983 at 0°; 0·2212 at 100°; and 0·2442 at 200° at one atm. press., while at 30 atm. press., the sp. ht. was 0·278. H. N. Mercer gave 0·2185; and W. Heuse, 0·210 at 20°; 0·200 at —30°; and 0·190 at —70°. K. Scheel and W. Heuse, for the mol. heat, $C_p=9{\cdot}24$ at 20°; 8·79 at —30°; and 8·37, at —70°; and for the ratio of the two sp. hts., P. L. Dulong gave 1·253 at 20°; A. C. G. Suermann, 1·36; A. Cazin, 1·285 at 15°; A. Masson, 1·293 at 0°; T. Martini, 1·354 at 7°; G. Schweikert, 1·283 at 0°; A. Wüllner, 1·311 at 0°, and 1·272 at 100°; A. Leduc, 1·324 at ordinary temp.; J. R. Partington and W. G. Shilling, 1·302; H. N. Mercer, 1·261; and W. Heuse, 1·28 at 20°; 1·31 at —30°; and 1·34 at —70°. W. G. Shilling gave for the mol. ht. at constant vol., $C_v=6{\cdot}629+0{\cdot}00069\theta-0{\cdot}0_5241\theta^2$; and at constant press., $C_p=8{\cdot}659+0{\cdot}00677\theta-0{\cdot}0_5222\theta^2$. A. Eucken and E. Donath gave $C_p=7{\cdot}39$ for the solid at —125·25°.

Nitrous oxide gas is easily liquefied. In 1823, M. Faraday[10] heated thoroughly dried ammonium nitrate in one leg of a Λ-tube, and on cooling the other leg of the tube, obtained two liquids; one a soln. of nitrous oxide in water, and the other water in nitrous oxide. It is doubtful if J. H. Niemann prepared the liquid gas in in this way. The liquefaction by compression and cooling has been described by

G. S. Newth, M. Thilorier, L. P. Cailletet, J. H. Debray, J. O. Natterer, T. Wills, and others. Liquid nitrous oxide, contained in steel cylinders holding up to about 50 lbs. and eq. to 430 c. ft. of gas, is on the market. In 1845, M. Faraday cooled the liquid in a bath of solid carbon dioxide and ether below —100°, and obtained colourless crystals of nitrous oxide; C. Despretz found that the liquid in a silver dish in vacuo froze readily to a snow-like mass; and J. A. Natterer obtained solid, snow-like nitrous oxide by allowing the liquid to stream through a fine opening into the air. W. Ramsay and J. Shields found the **melting point** of the solid to be —102·3°. M. Faraday estimated —100°; T. Wills, —99°; J. A. Natterer, —115°; and P. A. Guye and G. Drouginine, —105·8°. For the **boiling point,** H. V. Regnault gave —87·9° at 767·3 mm.; T. Willis, —92°; L. Grunmach, —89·4° at 760 mm.; F. W. Bergstrom, —89·5°; P. A. Guye and G. Drouginine, —89·8°; W. Ramsay and J. Shields, —89·8° at 760 mm.; M. A. Hunter, —87° at 760, and —89·1° at 660 mm.; G. W. Burrell and I. W. Robertson, —88·7° at 760 mm.; and F. W. Bergstrom, —89·5°±0·2°. E. Cardoso and E. Arni found the **critical opalescence** extended from 36·0° to 36·5° and had a maximum at 63·3°. J. A. Muller gave 1·359 for the degree of polymerization in the critical state. J. Dewar gave 35·4° for the **critical temperature;** P. Villard, 38·8°; J. P. Kuenen, 36·0°; W. J. Jannssen, 36·4°; L. P. Cailletet and E. Mathias, 37·0°; and E. Cardoso and E. Arni, 36·50°. The subject was studied by W. Herz. For the **critical pressure,** J. Dewar gave 75 atm.; W. J. Jannssen, 73·07 atm.; and P. Villard, 77·5 atm.; and E. Cardoso and E. Arni, 71·65 atm. L. P. Cailletet and E. Mathias gave 0·0048 for the **critical volume,** and 0·41 for the **critical density;** P. Villard gave 0·454 for the critical density. W. Herz examined the relations of the critical constants of this oxide. S. F. Pickering gave for the best representative values T_c=309·6° K.; p_c=71·7 atm.; and D_c=0·45. L. P. Cailletet and E. Mathias gave for the **heat of vaporization,** 66·9 cals. per gram at —20°; 59·7 cals. at 0°; 43·7 cals. at 20°; and 13·5 cals. at 35°; and D. L. Hammick gave 69·4 Cals. G. A. Burrell and I. W. Robertson gave 5·626 cals. per mol. as the average heat of evaporation at about —90°. H. Crompton calculated data in agreement with L. P. Cailletet and E. Mathias's results. A. Eucken and E. Donath gave for the heat of vaporization of solid nitrous oxide 5822 cals. at —137·5°, and 5695 cals. at —113°.

J. Thomsen[11] found the **heat of formation** of gaseous nitrous oxide from its elements to be —18·32 Cals.; and M. Berthelot, —20·6 Cals. for the gas, —18·0 Cals. for the liquid; and —14·4 for the gas in aq. soln. J. Thomsen gave for (NO,N_2), 3·255 Cals. M. Berthelot and P. Vieille calculated the temp. of combustion of a mixture of nitrous oxide and cyanogen to be 3596°–4149°. J. C. Thomlinson calculated what he called the thermochemical eq. of the nitrogen contained in nitrous oxide—*vide infra.*

P. L. Dulong[12] gave for the **index of refraction** of nitrous oxide 1·000507, for white light; J. Jamin, 1·000507 for red light; H. Becquerel, for Na-light, 1·0005159; and E. Mascart, 0·0005084 for Na-light at 0° and 760 mm. If λ denotes the wave-length, the index of refraction $\mu=A(1+0{\cdot}0127\lambda^{-1})$. C. and M. Cuthbertson gave 1·00051415 for λ=477·9μμ; 0·00051145 for λ=520·9μμ; 0·00051000 for λ=546·1μμ=0·00050848 for λ=579·0μμ; and 0·00050544 for λ=670·8μμ. They represented their results by the formula $\mu-1=5{\cdot}6685\times10^{27}(11416\times10^{27}-\lambda^2)^{-1}$. M. Faraday said that the liquid refracts light less than all other liquids he tried. L. Bleekrode gave for the refractive index of the gas 1·000503, and 1·204 for the liquid. He also gave $(\mu-1)/D$=0·255 for the gas, and 0·235 for the liquid; while $(\mu^2-1)/(\mu^2+2)D$=0·170 for the gas, and 0·150 for the liquid. W. Herz studied the refraction of nitrous oxide. J. Koch measured the **dispersion.** H. Becquerel gave for the **magnetic rotation** of the plane of polarization of the gas with Na-light, 16·02, or 0·00393 with that of liquid carbon disulphide. C. E. Guye and R. Rudy studied the electromagnetic rotation of nitrous oxide. C. V. Raman and K. S. Krishnan gave $0{\cdot}48\times10^{-10}$ for Kerr's constant at 20°. Lord Rayleigh, and J. Cabannes and J. Granier studied the polarization of light laterally diffused in nitrous oxide. F. Holweck studied the absorption spectrum. A. Dufour found that in the neighbourhood of the bands $\lambda=585{\cdot}49\mu\mu$ and 584·68, the ordinary effect is produced, but with the bands $\lambda=592{\cdot}54\mu\mu$ and $585{\cdot}69\mu\mu$, the inverse effect is obtained. W. H. Bair, and H. O. Kneser studied the **spectrum** of nitrous oxide; and S. W. Leifson, the ultra-violet absorption spectrum. M. F. Skinker and J. V. White investigated the motion of electrons in nitrous oxide.

M. A. Hunter[13] showed that platinum electrodes are not polarized by nitrous oxide, and he estimated that the **oxidation potential** of nitrous oxide is about 0·39 volt higher than that of oxygen. G. Gehlhoff studied the cathode fall of potential during an electric discharge in a vacuum tube; E. P. Metcalfe, the ionization of the gas; L. B. Loeb, and M. F. Skinker and J. V. White, the mobilities of ions in the gas; W. G. Palmer, the effect of nitrous oxide on the coherer in detecting electric waves. F. M. Bishop found the ionizing potential to be the same as that of nitrogen. The **dielectric constant** of nitrous oxide gas was found by L. Boltzmann[14] to be 1·000497, and by J. Clemencic, 1·000579. F. Linde found the dielectric constant of liquid nitrous oxide to be 1·643 at −6°; 1·591 at −0·5°; 1·582 at 4°; 1·55 at 10°; and 1·522 at 14·5°; and for nitrous oxide gas at 15°, 1·070 at 39 atm. press.; 1·051 at 29·8 atm.; 1·026 at 19·9 atm.; and 1·010 at 9·4 atm. W. Herz studied some relations between the dielectric constant and the physical properties. G. Quincke obtained $+0{\cdot}12\times10^{-6}$ mass units for the **magnetic susceptibility** of nitrous oxide, at 16° and 40 atm. press.; T. Soné said that nitrous oxide is diamagnetic with the sp. susceptibility $-0{\cdot}43\times10^{-6}$, and this constant has the same value whether the compound is liquid or gaseous. The subject was studied by N. W. Taylor and G. N. Lewis, and A. E. Oxley.

The solubility of nitrous oxide in different solvents.—H. Davy[15] said that at ordinary temp. one vol. of *water* dissolves 0·54 vol. of the gas, and J. Priestley said that the dissolved gas is driven unchanged from the boiling liquid. The solubilities measured by N. T. de Saussure, W. Henry, J. Dalton, and A. M. Pleischl ranged from 0·708 to 0·80. These numbers are not discordant with later values obtained at specified temp. by W. Knopp, V. Gordon, G. Geffcken, W. Roth, etc. R. Bunsen gave for the coeff. of absorption, β, and G. Geffcken for the solubility, S, expressed as a ratio of the vol. of gas absorbed at θ° to the vol. of the absorbing liquid:

	5°	10°	15°	20°	25°
β . . .	1·0950	0·9196	0·7778	0·6700	0·5961
S . . .	1·067	0·9101	0·7784	0·6756	0·5992

L. Carius, and G. Wiedemann represented their results at θ° by $\beta=1{\cdot}30521-0{\cdot}0453620\theta+0{\cdot}00068430\theta^2$; and M. Bellati and S. Lussana, $\beta=1{\cdot}30224-0{\cdot}046184\theta+0{\cdot}0007190 4\theta^2$. The effect of press. on the solubility was found by A. Findlay and O. R. Howell to be independent of press. within 758 and 1362 mm. in that the ratio of the conc. of the gas in the gaseous and solution phases remained constant at 0·592. Liquid nitrous oxide is not completely miscible with water. As shown by M. Faraday, and T. Wills, there is formed a soln. of nitrous oxide in water on which floats what is probably a soln. of water in liquid nitrous oxide. M. L. Nichols and I. A. Derbigny stated that nitrous oxide forms with water a soln. having acidic properties: $N_2O+H_2O=(NOH)_2$. According to P. Villard, water forms with nitrous oxide a crystalline **hexahydrated nitrous oxide,** $N_2O.6H_2O$. It is produced by keeping a mixture of liquid nitrous oxide and water in the presence of mercury in a sealed tube standing for some time in ice. The tube, at 0°, is opened and the gas allowed to escape. The acicular, or tabular crystals are said to belong to the cubic system; to have a sp. gr. 1·15; to be stable below 0° at atm. press.; and to have a heat of formation $(N_2O,6H_2O)=15$ Cals. G. Tammann and G. J. R. Krige found the dissociation press., p, at the temp. θ to be $\theta=19{\cdot}4\ (\log p-0{\cdot}9795)$.

G. Lunge measured the solubility of the oxide in sulphuric acid and found that 100 vols. of acid of sp. gr. 1·84 dissolved 75·7 vols. nitrous oxide; sp. gr. 1·80, 66·0 vols.; sp. gr. 1·705, 39·1 vols.; sp. gr. 1·45, 41·6 vols.; and sp. gr. 1·25, 33·0 vols.

G. Geffcken obtained the following results for the solubility, S, in *hydrochloric, nitric, and sulphuric acids;* and W. Roth, for the coeff. of absorption, β, for *phosphoric and oxalic acids:*

		5°	15°	25°
S, HCl	18·22 per cent.	—	0·755	0·577
	72·90 ,,	—	0·716	0·557

W. Manchot found that the results with sulphuric, nitric, and hydrochloric acid soln. differ from those with salts, for, with rising concentration, the solubility first falls, reaches a minimum, and then increases—Fig. 67. W. Knopp found that at 20° aq. soln. containing 15·15, 158·4, and 344·0 grms. of *propionic acid* per litre have the coeff. of absorption: 0·6323, 0·6504, and 0·7219 respectively. Using S for the solubility as indicated above, and β for the coeff. of absorption, G. Geffcken found for soln. with 53·52 grms. of *ammonium chloride* per litre, $S=0·691$ at 15°, and $S=0·529$ at 25°; and with 42·48 grms. of *lithium chloride,* $S=0·623$ at 15°, and 0·483 at 25°. Observations with lithium chloride were also made by V. Gordon, who found for soln. with 12·78 grms. of *sodium chloride* per litre, $\beta=0·634$ at 5°, and 0·386 at 20°. W. Roth made more detailed observations with this salt. G. Geffcken gave for the soln. with 74·6 grms. of *potassium chloride* per litre, $S=0·616$ at 15°, and 0·475 at 25°. Observations with potassium chloride were also made by V. Gordon, and N. T. de Saussure. G. Geffcken also found for soln. with 120·95 grms. of *rubidium chloride* per litre, $S=0·625$ at 15°, and 0·483 at 25°; for soln. with 84·17 grms. of *cæsium chloride* per litre, $S=0·710$ at 15°, and 0·544 at 25°. V. Gordon found for soln. with 13·99 grms. of *calcium chloride* per litre, $\beta=0·510$ at 5°, and 0·328 at 20°; and for soln. with 13·24 grms. of *strontium chloride* per litre, $\beta=0·644$ at 5°, and 0·391 at 20°. G. Geffcken gave for soln. with 119·11 grms. of *potassium bromide* per litre, $S=0·627$ at 15°, and 0·485 at 25°; for soln. with 166·12 grms. of *potassium iodide* per litre, $S=0·633$ at 15°, and 0·492 at 25°. V. Gordon gave for soln. with 8·56 grms. of *lithium sulphate* per litre, $\beta=0·646$ at 5°, and 0·415 at 20°; for soln. with 12·44 grms. of *sodium sulphate* per litre, $\beta=0·559$ at 5°, and 0·354 at 20°; for soln. with 4·78 grms. of *potassium sulphate* per litre, $\beta=0·918$ at 5°, and 0·542 at 20°; and for soln. with 10·78 grms. of *magnesium sulphate* per litre, $\beta=0·569$ at 5°, and 0·346 at 20°. G. Geffcken found that 100 vols. of conc. soln. of *ferrous sulphate* absorb 19·5 vols. of nitrous oxide. W. Knopp gave for soln. with 11·37 and 95·30 grms. of *sodium nitrate* per litre, at 20°, respectively $\beta=0·6089$ and 0·4926; and for soln. with 10·74 and 118·2 grms. of *potassium nitrate* per litre at 20°, respectively $\beta=0·6173$ and 0·5196. G. Lunge found that 100 vols. of a soln. of *sodium hydroxide,* sp. gr. 1·10, absorb 23·1 vols. of nitrous oxide; and 100 vols. of a soln. of *potassium hydroxide,* sp. gr. 1·12, absorb 18·7 vols. of nitrous oxide. G. Geffcken gave for soln. with 28·08 and 56·16 grms. of potassium hydroxide per litre, $S=0·668$ and 0·559 respectively at 15°; and 0·514 and 0·436 at 25°; with 100 vols. of sodium hydroxide sat. with *pyrogallol,* 28 vols. of nitrous oxide were absorbed. W. Manchot's results with soln. of the chlorides of ammonium, potassium, sodium, calcium, and barium; bromides of ammonium, potassium, and sodium; nitrates of ammonium, potassium, sodium, copper, calcium, magnesium, zinc, cadmium, and aluminium; sulphates of ammonium, potassium, sodium, magnesium, zinc, aluminium, manganese, iron (ous and ic), cobalt, nickel, and chromium; sodium hydrophosphate, sodium orthophosphate, and potassium periodate, are illustrated in Fig. 67.

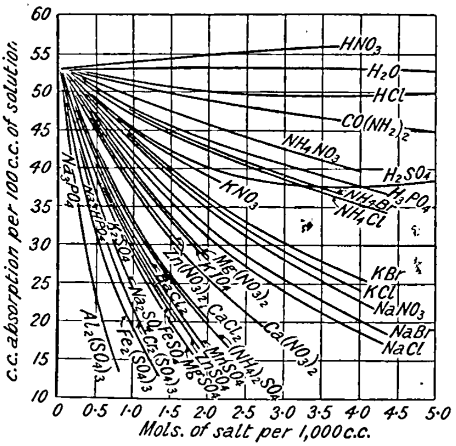

FIG. 67.—The Solubility of Nitrous Oxide in Salt Solutions.

W. Manchot calculated the results to show the effect of equal weights of water in the soln., and he attempted to calculate the number of mols of water required by the various ions.

A. Findlay and co-workers measured the effect of press. on the solubility of nitrous oxide on colloidal soln. of *ferric hydroxide* of different conc. Thus, with 0·625, 1·49, and 4·061 grms. of ferric hydroxide per 100 c.c. of soln., the solubility of nitrous oxide is respectively 0·590, 0·586, and 0·578 at press. approximating 750 mm., 0·584, 0·577, and 0·571 at press. approximating 930 mm., and 0·588, 0·586, and 0·580 at press. approximating 1350 mm. The solubility in colloidal soln. of *arsenious sulphide* is similar; G. Geffcken also measured this effect with ferric hydroxide and arsenious sulphide. A. Findlay and H. J. M. Creighton found that the solubility in silicic acid increases with increasing conc. of *silicic acid*, and with increasing press.

H. Davy found nitrous oxide is soluble in *alcohol* and *ether*; and N. T. de Saussure said that 100 vols. of alcohol of sp. gr. 0·840 absorb 153 vols. of gas. R. Bunsen gave for the solubility of nitrous oxide in alcohol, expressed in vols. of gas, reduced to 0° and 760 mm., per vol. of alcohol:

	0°	5°	10°	15°	20°	24°
N_2O . .	4·178	3·844	3·541	3·268	3·025	2·853

L. Carius found the absorption coeff. of nitrous oxide in alcohol at 760 mm. press. at $\theta°$ to be $\beta=4{\cdot}17805-0{\cdot}0698160\theta+0{\cdot}0006090\theta^2$; and M. Bellati and S. Lussana, $\beta=4{\cdot}19044-0{\cdot}074477\theta+0{\cdot}0007857\theta^2$. G. Lunge's proposal to determine the gas by absorption with absolute alcohol is, according to L. W. Winkler, too inexact. W. Kunerth found the solubility of nitrous oxide at 20° in water, 0·675; in *methyl alcohol*, 3·32; in ethyl alcohol, 2·99; in *isoamyl alcohol*, 2·47; in *acetone*, 6·03; in *acetic acid*, 4·85; in *pyridine*, 3·58; in *chloroform*, 5·60; in *benzaldehyde*, 3·15; in *aniline*, 1·48; in *amyl acetate*, 5·14; and in ethylene bromide, 2·81 c.c. of gas at the prevailing press. per c.c. of solvent. W. Knopp found the coeff. of absorption of nitrous oxide in soln. with 30·43 and 316·4 grms. of *chloral hydrate* per litre at 20° to be respectively 0·618 and 0·567. W. Roth found for soln. with 3·46 and 16·24 per cent. of *glycerol* $\beta=1{\cdot}097$ and 0·959 respectively at 5°; and 0·556 and 0·508 respectively at 25°; likewise for soln. with 3·31 and 9·97 per cent. of *urea*, $\beta=1{\cdot}104$ and 1·069 respectively at 5°, and 0·569 in both cases at 25°. S. H. Steiner found that the coeff. of absorption of soln. with 1·699 and 0·520 mols of *cane-sugar* per litre at 15° is 0·0892 and 0·1561 respectively. A. Findlay and co-workers found with increasing conc. of *dextrin*, the solubility fell from 0·549 with 6·98 grms. of dextrin per 100 c.c. to 0·503 with 20·30 grms. The solubility increased with increasing press. Analogous results were obtained with *starch*, *gelatin*, and *glycogen*; while with *egg-albumen*, and *serum-albumen* the solubility curves give a minimum with increasing press. being 0·583, 0·579, and 0·591 respectively at 746, 978, and 395 atm. press. for a soln. with 0·32 grm. of *serum-albumen* per 100 c.c. Hence, the solubility with these colloidal soln. no longer follows Henry's law. This may be due to a polymerization of the gas or to adsorption effects. R. Siebeck, and A. Findlay and co-workers measured the solubility of nitrous oxide in *blood*. The first-named observed that the absorption coeff. of water for nitrous oxide is smaller than that of blood. The increased absorption is not due to the plasma, the coeff. of which is 97·5 per cent. of that of water. On the other hand, a soln. of red corpuscles has a markedly greater coeff. than water, and the absorption in this soln. obeys Henry's law, and is independent of the absorption of carbon dioxide and oxygen. Nitrous oxide is soluble in *fixed and volatile oils*. N. T. de Saussure found that 100 vols. of rectified *naphtha* of sp. gr. 0·784 absorb 254 vols. of gas; 100 vols. of *turpentine*, 250–270 vols. of gas; 100 vols. of *oil of lavender* of sp. gr. 0·880 absorb 275 vols.; and 100 vols. of *olive oil* of sp. gr. 0·915, 150 vols. of gas. S. Gniewasz and A. Walfisz found for *petroleum*, at 10°, $\theta=2{\cdot}49$, and at 20°, 2·11.

According to P. A. Favre, one c.c. of *charcoal* absorbs 99 c.c. of nitrous oxide; and, according to N. T. de Saussure, 40 c.c. The heat of absorption is 3718 cals. per equivalent. A. Findlay and H. J. M. Creighton found that with charcoal suspended in water and nitrous oxide,

Pressure	950	1000	1050	1150	1250	1350
Gas absorbed by solid C_1 . .	0·0059	0·0085	0·0109	0·0151	0·0200	0·02
Gas dissolved by water, C_2 .	0·1332	0·1402	0·1472	0·1613	0·1753	0·18
C_1/C_2	0·058	0·048	0·043	0·045	0·047	0·05

L. B. Richardson and J. C. Woodhouse studied the absorption of mixtures of carbon dioxide and nitrous oxide by charcoal; S. J. Gregg, the heat of adsorption; D. H. Bangham and F. P. Burt, the adsorption of nitrous oxide by *glass*; and W. A. Patrick and co-workers, by *silica gel* near the critical temp. of the gas.

The chemical properties of nitrous oxide.—Nitrous oxide was analyzed by

H. Davy,[16] J. L. Gay Lussac and L. J. Thénard, and J. R. Deiman and co-workers. The results of H. Davy are in harmony with the empirical formula N_2O. This also agrees with analyses by A. Jaquerod and S. Bogdan, and E. H. Keiser. The density of the gas is in agreement with the simplest formula. The mol. is generally supposed to have two tervalent nitrogen atoms, and to be constituted:

$$\begin{matrix} N \\ \vdots \\ N \end{matrix} > O$$

—not N.O.N by analogy with H.O.H. There are other possibilities, *e.g.* W. A. Noyes favoured, but W. T. Hall objected to the formula $O{=}N{\equiv}N$ recommended by H. Henstock. G. Kirsch, A. E. Oxley, J. R. Partington, A. O. Rankine, C. D. Niven, and A. W. C. Menzies discussed the at. and mol. structure. According to K. A. Hofmann, and L. Pauling and S. B. Hendricks, the chemical evidence favours the constitution $N{\equiv}N{=}O$, rather than $N_2{>}O$. J. C. Thomlinson tried to calculate the eq. of nitrogen in nitrous oxide from thermochemical data; and he considered that the results agree with the assumption that nitrous oxide contains quinquevalent nitrogen; G. le Bas said that the mol. vol. agrees with the 3-membered ring formula

$$\begin{matrix} \cdot{<}N \\ \vdots \\ \cdot{<}N \end{matrix} > O$$

A. O. Rankine found that the mols. of nitrous oxide and carbon dioxide behave physically as if they had the same size, shape, and electronic structure. I. Langmuir compared the physical properties of carbon dioxide and of nitrous oxide, and the similarity was attributed to a like electronic structure—*vide* **4.** 27, 4, Fig. 30. G. Kirsch made observations on the electronic structure of the molecule; and M. L. Huggins made estimates of the interatomic distances.

Nitrous oxide, or a gas with an analogous composition, is the anhydride of hyponitrous acid, $H_2N_2O_2$, and could be called **hyponitrous anhydride.** Owing to our defective notation, it cannot be called nitrous anhydride by analogy with the nomenclature employed in many other cases. Nitrous anhydride, N_2O_3, is the anhydride of nitrous acid, HNO_2. To adjust the nomenclature, nitrous oxide would have to be called **hyponitrous oxide.** While the action of water on nitrous or hyponitrous anhydride does not form hyponitrous acid, yet the dehydration of hyponitrous acid by conc. sulphuric acid forms nitrous or hyponitrous oxide: $H_2SO_4+H_2N_2O_2=H_2SO_4.H_2O+N_2O$.

J. Priestley [17] showed that nitrous oxide is decomposed into its elements when passed through a red-hot porcelain tube, and at the same time a higher oxide is formed. M. Berthelot found that after heating for half an hour at 520°, about 1·5 per cent. of the gas is decomposed, and at the same time, some of the higher oxides are formed. C. Langer and V. Meyer observed that the decomposition is complete at 900°. According to G. T. Kemp, C. Winkler's proposal to estimate the nitrous oxide in some gaseous mixtures by decomposing this gas: $2N_2O=2N_2+O$ by passing it over red-hot palladium, is inexact. M. A. Hunter found that the course of the decomposition at 713°, 805°, and 895° corresponds with that of a bimolecular reaction; and the influence of temp. on the velocity constant, k, is represented by $\log k=31800T+24{\cdot}12$. The influence of moisture on the reaction is not appreciable. S. Dushman studied these results. L. Maquenne found that when a small quantity of mercury fulminate is exploded in contact with nitrous oxide, the latter is decomposed. According to E. Briner and A. Wroczynsky, nitrous oxide is more stable than nitric oxide in that it requires a higher temp. to show an appreciable decomposition. At 600 atm. and 420°, it suffers a slight decomposition. According to C. N. Hinshelwood and co-workers, the heterogeneous thermal decomposition of nitrous oxide on the surface of a heated platinum wire between 600° and 1200° is retarded by the presence of oxygen and proceeds at a relatively faster rate at low than at high press.

The velocity of the reaction is represented by the equation $-d[N_2O]/dt = k[N_2O]/(1+b[O_2])$, and the heat of activation in the catalytic reaction is 32,500 cals. per mol. This reaction is unimolecular, whereas the homogeneous thermal decomposition of nitrous oxide is bimolecular and its heat of activation is much greater; the platinum surface in the heterogeneous reaction acts as an acceptor for atomic oxygen, the nitrous oxide probably giving its oxygen atom to the platinum, thereby forming a retarding film of at. oxygen. They also studied the decomposition of nitrous oxide on the surface of heated gold and found the unimolecular process is a true wall-reaction. S. Uchida found that the reaction is of the first order, and that the velocity constant of the decomposition of nitric oxide is 0·39 with platinum gauze as catalyst, and 0·013 with ferric oxide as catalyst at a temp. of 600°. R. C. Tolman studied the different ways of activating the molecules in the bimolecular reaction $2N_2O=2N_2+O_2$. E. Briner and co-workers observed that when nitrous oxide is circulated through a heated fused silica tube, at 1300°, 25 per cent. of the gas is converted into nitric oxide, and the amount is lowered by the presence of powdered quartz or platinum. It is suggested that the nitrous oxide breaks down simultaneously in two ways, $N_2O \rightarrow N_2+\frac{1}{2}O_2+20{\cdot}6$ Cals., and $N_2O \rightarrow NO+\frac{1}{2}N_2-0{\cdot}9$ Cal. The reaction was studied by C. Meiner, F. A. Constable, and E. J. Bowen. J. Priestley found that the gas is decomposed by long-continued sparking; and W. R. Grove added that at the same time there is an increase in volume from 1 to 1·5; with a more protracted action, red fumes of the higher oxides appear. These results were confirmed by H. Buff and A. W. Hofmann, and M. Berthelot. S. S. Joshi studied the decomposition of nitrous oxide by the silent electrical discharge in the press. range 110–820 mm. The end-products are nitrogen and oxygen, but the intermediate products indicate that the reaction actually involves two simultaneous reactions: $2N_2O=2NO+N_2$ and $2N_2O=2N_2+O_2$, followed by $2NO+O_2=2NO_2$, or else it involves the three consecutive reactions: $4N_2O=4NO+2N_2$; $2NO=N_2+O_2$; and $2NO+O_2=2NO_2$. The time required for total decomposition increases rapidly with increase of gas press., and the mean rate of decomposition increases with an increase in the potential applied to the reaction vessel, and diminishes as the gas press. increases. A. Geitz studied the dissociation of nitrous oxide by the high-tension arc-flame; and E. Wourtzel, by a stream of α-rays from radium: $N_2O=NO+N$. D. Berthelot and H. Gaudechon observed that nitrous oxide is partly decomposed into its elements when exposed to the light from a mercury quartz lamp, and the oxygen so formed unites with the undecomposed gas to form higher oxides. E. Warburg and E. Regener found that nitrous oxide is decomposed by radiations of short wave-length from a spark discharge. The wave-length of the active ray is under $0{\cdot}3\mu$.

In his early work on this gas, J. Priestley[18] noticed that nitrous oxide is not combustible; a candle will burn in the gas more brilliantly than in air; a glowing splint, when immersed in the gas, bursts into flame. J. Priestley said:

> Sometimes I have perceived the flame of a candle in the circumstances to be twice as large as it is naturally, and sometimes not less than five or six times larger; and yet without anything like an explosion, as in the firing of the weakest inflammable air. . . . At the time of my first publication on this subject, I should not have hesitated to pronounce as impossible (that) air in which a candle burns naturally and freely, (would be) in the highest degree noxious to animals, insomuch that they die the moment they are put in it.

H. B. Dixon and W. F. Higgins found that when the air feeding the flame of **hydrogen,** methane, ethylene, or propylene is replaced by nitrous oxide, there is a pretty transformation scene. It is possible to read by the hydrogen flame in nitrous oxide although the flame is almost invisible in air. Fig. 68 illustrates the great contrast between the two flames. The hydrocarbons give a core of white light with an apricot-coloured, and then a large, greenish-grey sheath. The flames are magnified roughly five times in height and twice in diameter. No peroxide could be detected in the interconal gases, but it is found in the gases of the outer flame.

The ignition points, $\theta°$, of hydrogen, ethylene, and propylene in nitrous oxide, with a 0·5 sec. lag, at different press., p mm., are :

	p	1000	760	550	400	250	150	100
θ	H_2	594°	597°	572°	549°	524°	504°	—
	C_2H_4	—	592°	605°	605°	592°	578°	570°
	C_3H_6	—	586°	605°	623°	620°	608°	—

All these gases ignite in nitrous oxide at a lower temp. than they do in air. J. Priestley, H. Davy, and W. Henry observed that if nitrous oxide be mixed with hydrogen in equal vols., and ignited by an electric spark, or a red-hot tube, the detonation is attended by the formation of water and nitrogen: $N_2O+H_2=N_2+H_2O$; if less hydrogen be used, some nitric acid is produced ; the reaction is utilized in gas analysis. G. T. Kemp, and G. Lunge obtained high results, but O. von Dumreicher, L. H. Milligan, and W. Hempel obtained satisfactory results when an excess of hydrogen is used—say 2 or 3 times the vol. of that of the nitrous oxide.

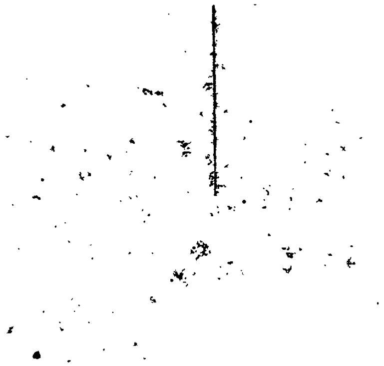

FIG. 68.—Flames of Hydrogen in Nitrous Oxide and in Air.

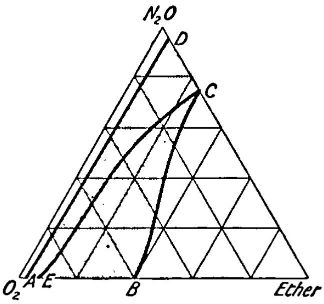

FIG. 69.—Explosive Limits with $N_2O-(C_2H_5)_2O-O_2$ (and Air).

W. K. Hutchison and C. N. Hinshelwood measured the rate of the reaction $N_2O+H_2=N_2+H_2O$ (liquid) on the surface of gold wire at 704° and 880°. Both gases are adsorbed independently by the gold, and the rate of the reaction tends to a limiting value as the press. of each gas is increased showing that the surface of the gold approaches a state of saturation. With hydrogen, there is a complication due to the absorption of hydrogen as distinct from adsorption. H. B. Dixon found the velocity of explosion of mixtures of nitrous oxide and hydrogen, $H_2+N_2O=H_2O+H_2$, to be 2305 metres per second ; and M. Berthelot and P. Vieille, 2284 metres per second. According to W. P. Jorissen and B. L. Ongkiehong, the explosive regions with mixtures $N_2O—(C_2H_5)_2O—O_2$ can be represented by the regions *ABCD*, Fig. 69 ; and with mixtures $N_2O—(C_2H_5)_2O$—air, by the region *ADCE*. On adding air to the mixture with oxygen, the line *CB*, revolving about *C*, moves to the left, and finally coincides with *CE*. If the ignition spark is strong enough to start a reaction with $H_2O—O$ mixture, which propagates itself, the line *AD* will revolve about *A* and cut the left side of the triangle. C. Winkler recommended estimating the nitrous oxide in some gaseous mixtures by adding an excess of hydrogen, and passing the mixture over heated platinized asbestos: $N_2O+H_2=H_2O+N_2$. L. Duparc and co-workers found that while hydrogen in the presence of metals of the platinum group reduces nitric oxide to ammonia, nitrous oxide is reduced to nitrogen. H. S. Taylor and A. L. Marshall studied the reduction of the gas by the activated hydrogen. The reduction of nitrous oxide to ammonia by hydrogen in the presence of platinum sponge or platinum or palladium black has been studied by J. W. Döbereiner, P. L. Dulong and L. J. Thènard, F. Kuhlmann, M. A. Hunter, C. N. Hinshelwood, H. S. Taylor,

C. Montemartini, etc.—*vide* ammonia; and in the presence of nickel and copper, by P. Sabatier and J. B. Senderens. According to P. A. Guye and F. Schneider, nitrous oxide is reduced by nickel and hydrogen much more slowly than is the case with nitric oxide. No nitrous oxide is formed during the reduction of nitric oxide by nickel and hydrogen, but it may be formed when nitric oxide is reduced by sulphur dioxide. M. Berthelot could not detect the formation of a higher oxide when a mixture of **oxygen** and nitrous oxide is heated to dull redness. M. Berthelot and H. Gaudechon found that a mixture of nitrous oxide and oxygen forms higher nitrogen oxides when exposed to ultra-violet light. For the action of water, *vide supra*. The gas, and an aq. soln. of the gas, has no action on vegetable colours—litmus, etc.

H. Moissan and P. Lebeau found that **fluorine** does not react with nitrous oxide at a dull red heat. If a mixture of the two gases be heated electrically by means of a platinum spiral, platinum fluoride is formed at 400°, or if the two gases are heated to redness in a glass vessel, silicon fluoride and oxygen are formed, whilst the nitrous oxide remains unaltered. When a mixture of nitrous oxide and fluorine is submitted to the action of an induction spark in the presence of mercury, there is a complex reaction, the mercury is attacked, and the final gaseous mixture contains oxygen, nitrogen, and nitrous oxide, but no compound of nitrogen and fluorine. A. J. Balard did not detect any reaction between nitrous oxide and **chlorine monoxide** in the cold. J. B. A. Dumas observed no reaction between **iodine** and liquid nitrous oxide. O. von Dumreicher observed that nitrous oxide forms a white cloud when treated with **hydrogen iodide,** the cloud gradually reddens, and crystals of iodine appear: $N_2O+10HI=2NH_4I+H_2O+4I_2$. K. A. Hofmann and co-workers said that probably on account of its saturated nature, nitrous oxide does not react with potassium chloride at 360°, and it is also very sluggish in its action towards hydrogen and carbon monoxide in contrast with the vigorous action of potassium chlorate and ammonia.

H. Davy found that feebly burning **sulphur** continues burning vigorously in the gas, with a bright greenish-blue flame; sulphur dioxide is formed, and one vol. of nitrous oxide gives one vol. of nitrogen. According to A. Stavenhagen and E. Schuchard, if the combustion of sulphur in nitrous oxide be carried out in a large glass vessel, the walls become covered with crystals of nitrosulphonic acid, and, at the same time, nitrogen peroxide is formed in quantity. Thus, nitrous oxide may be transformed into higher oxides of nitrogen without the use of electrical energy by simply burning sulphur in it, nitrosulphonic acid anhydride or its decomposition products being formed at the same time. J. B. A. Dumas observed no reaction between liquid nitrous oxide and sulphur. G. Chevrier, and M. Berthelot observed that a mixture of sulphur vapour and nitrous oxide is inflamed by an electric spark, forming sulphur dioxide and nitrosopyrosulphuric anhydride. A mixture of **hydrogen sulphide** and nitrous oxide, with an electric spark or at a red-heat, furnishes sulphur dioxide, water, and nitrogen. P. Pascal said that a high conc. of **sulphur dioxide** reduces nitrous oxide to nitrogen if the temp. be high. E. J. B. Willey and E. K. Rideal found that nitrous oxide is not decomposed by active **nitrogen.** A mixture of nitrous oxide and **ammonia** is reduced by an electric spark, or when heated to redness, forming nitrogen and water. A. Joannis found that when nitrous oxide is passed into a soln. of potassium or sodium in liquid ammonia, an amide is formed: $N_2O+2KNH_3=KNH_2+NH_3+KOH+N_2$, and with a more protracted action, a nitride is produced: $2KNH_2+N_2O=KN_3+KOH+NH_3$. Unlike oxygen, when nitrous oxide is mixed with a little **nitric oxide,** it does not produce red fumes, nor suffer a diminution in vol. J. R. Deiman and co-workers observed that fuming **nitric acid** reduces the vol. of nitrous oxide, and P. T. Austen, that moist nitrous oxide reacts with the vapour of nitric acid, forming ammonium nitrate. F. Raschig observed that **nitrous acid** reacts with nitrous oxide, forming nitric oxide. H. B. Dixon and J. D. Peterkin observed a slight expansion on mixing nitrous oxide and **nitrogen peroxide,** thus indicating a slight dissociation of the N_2O_4-mols. H. Davy found that **phosphorus** can be volatilized, or touched with a red-hot iron rod in an atm. of nitrous oxide without inflammation; but if a white-hot iron rod is used, or if the phosphorus be vigorously burning when immersed in the gas, it burns as brilliantly as in oxygen, forming phosphorus pentoxide, and some nitrogen peroxide. J. B. A. Dumas observed no reaction with liquid nitrous oxide and phosphorus. According to P. Thénard, spontaneously inflammable **phosphine** detonates with nitrous oxide at ordinary temp. The reaction was studied by J. J. Berzelius, T. Thomson, and J. B. A. Dumas; it is symbolized by $2PH_3+8N_2O=P_2O_5+3H_2O+8N_2$ (or $2H_3PO_4+8N_2$).

H. Davy found that glowing **carbon** burns as vigorously in nitrous oxide as in oxygen: $2N_2O+C=CO_2+2N_2$; but J. B. A. Dumas observed no reaction between liquid nitrous oxide and carbon, but a glowing piece of charcoal swims on the liquid while burning vigorously. H. Davy found that a mixture of **carbon monoxide** and nitrous oxide can be detonated by electric sparks; and that the same result occurs with a mixture of nitrous oxide and **cyanogen,** or of nitrous oxide and a **hydrocarbon.** W. Henry referred to the vivid combustion of a mixture of nitrous oxide and olefiant gas; and H. B. Dixon and W. F. Higgins' observations have been previously described. W. Henry, and G. T. Kemp recommended determining the nitrous oxide in some gaseous mixtures by adding about 7 vols. of carbon monoxide to one vol. of nitrous oxide, $CO+N_2O=CO_2+N_2$, and estimating the resulting carbon dioxide by absorption with alkali-lye. If the gases are moist there is a disturbing side reaction: $CO+H_2O=CO_2+H_2$. M. Berthelot and P. Vieille gave for the velocity of the explosion: $CO+N_2O=CO_2+N_2$, 1106 metres per second. J. B. A. Dumas found that a mixture of liquid nitrous oxide and **carbon disulphide,** or **alcohol,** or **ether** will freeze mercury, sulphuric acid, or nitric acid; and J. O. Natterer said that in vacuo a temp. of −140° can be obtained with a mixture of liquid nitrous oxide and carbon disulphide—*vide supra* for the combustion of ether in the gas. Heated **boron** burns in the gas, forming, according to H. Davy, boric oxide, and, according to H. St. C. Deville and F. Wöhler, some boron nitride.

J. L. Gay Lussac and L. J. Thénard found that when **sodium** or **potassium** is heated in the gas, the combustion is vigorous, forming alkali peroxide, and nitrite, as well as oxygen and nitrogen. P. Sabatier and J. B. Senderens found that **copper** above 150° is slowly transformed into cuprous oxide. E. Schröder and G. Tammann measured the rate of oxidation of copper by nitrous oxide. P. Sabatier and J. B. Senderens found that **magnesium** powder in contact with water and nitrous oxide reacts with the evolution of much hydrogen; **zinc** filings act similarly —hydrogen and nitrogen are produced together with some ammonia. H. Davy found that zinc is slowly oxidized at a red-heat. P. Sabatier and J. B. Senderens observed that **cadmium** is gradually oxidized by the gas at 300°. H. Davy found that **manganese** and **tin** are oxidized by the gas at a red-heat; and P. Sabatier and J. B. Senderens observed that **lead** is oxidized at 300°; **iron** burns in the gas below 170°, forming ferric oxide; and at ordinary temp., in the presence of moisture, nitrous oxide is reduced to nitrogen and some hydrogen is produced. J. Priestley said that iron filings burn in nitrous oxide as vigorously as in oxygen. E. Schröder and G. Tammann measured the rate of oxidation of iron and **nickel** by nitrous oxide. P. Sabatier and J. B. Senderens observed that **cobalt** burns in nitrous oxide at 230°, forming cobaltous oxide; nickel likewise forms green nickelous oxide; and **palladium hydride** at 250° produces water; while **palladium** itself is not changed. E. Schröder and G. Tammann compared the rates of oxidation of metal by oxygen, nitric oxide, and nitrous oxide.

J. Persoz said that nitrous oxide reacts with moist **potassium hydroxide,** forming nitric acid and ammonia, or ammonium nitrate, but later considered that these substances were derived from some ammonium nitrate mechanically mixed with the gas prepared from that salt. M. Berthelot could find no trace of ammonia when the nitrous oxide is passed over red-hot **soda-lime**; alcoholic potash at 100°–200°; or potash-lye at 300°. P. Sabatier and J. B. Senderens found that at 200°, nitrous oxide reacts with **sodium dioxide,** forming sodium nitrite and nitrogen; and with **barium dioxide** in an analogous manner at 500°–600°; **manganous oxide** at 350° forms Mn_3O_4 with inflammation; **tungsten dioxide** at 450° forms the blue oxide; **molybdenum monoxide** below 500° forms the violet oxide; **stannous oxide** at 400° forms stannic oxide; **cuprous oxide** at 350° is not changed; **lead dioxide** at 200° forms litharge and oxygen; **uranium dioxide** at 450° is not changed. V. Kohlschütter and K. Vogdt, and C. Friedheim discussed solid soln. of nitrous oxide and **uranium trioxide.** A. Wagner found that when nitrous oxide is passed over a heated mixture of **chromic oxide** and sodium carbonate, sodium chromate is produced. He recommended the reaction as a means of estimating nitrous oxide in some gaseous mixtures since nitric oxide does not react in this way. As a rule, nitrous oxide is fairly stable towards **oxidizing agents**; an alkaline soln. of **potassium permanganate** was found by J. A. Wanklyn and W. J. Cooper to be unaffected by nitrous oxide at 100°; and O. von Dumreicher observed that **stannous chloride** does not reduce nitrous oxide. Similarly, **stannous salts, alkali sulphides or sulphites,** and **ferrous salts** have no action on nitrous oxide; nor is the gas dissolved by soln. of ferrous salts—*confer* nitric oxide and soln. of ferrous salts. M. Coblens and J. K. Bernstein found that **titanous chloride** reduces nitrous oxide to ammonia. M. L. Nichols and I. A. Derbigny showed that in the reduction of nitrous oxide by stannous chloride, titanous chloride, and sodium sulphite, at 25°, ammonia, hydroxylamine, and nitrogen are respectively formed. The rate of reduction increases with increasing conc. of the reducing agent, decreases with a rise in temp., and, in the case of stannous chloride and titanous chloride, decreases with increased (hydrochloric) acid conc. The reduction of nitrous oxide by titanous chloride is catalyzed by platinum. The mechanism of the reduction is thought to depend on the initial formation of hyponitrous acid, according to the equation $N_2O+H_2O=(NOH)_2$, discussed by L. H. Milligan and G. R. Gillette, W. D. Bancroft, N. R. Dhar, and M. Coblens and J. K. Bernstein. M. L. Nichols and I. A. Derbigny found that the e.m.f. of soln. of the reducing agents with sat. soln. of nitrous acid, and varying amounts of hydrochloric acid, are in agreement with the observations of B. Neumann.

The physiological action of nitrous oxide.—Nitrous oxide has a slight odour, not disagreeable, and a sweetish taste; the aq. soln. also has a sweet taste. The gas may be respired for a short time—say less than four minutes, and it then produces remarkable effects suggestive of intoxication, hysteria, or delirium—particularly if mixed with about one-fourth its vol. of oxygen. There is first great hilarity, and ultimately loss of consciousness. H. Davy,[19] in his *Chemical and Philosophical Researches concerning Nitrous Oxide*, collected a number of observations made on the effects of the gas on different people. In his own case, he said that after breathing 15 quarts of the gas, " I danced about the laboratory as a madman "; and L. Edgworth said that after breathing the gas, " I burst into a violent fit of laughter, and capered about the room without having the power of restraining myself." The early observations of G. Cardone, J. L. Proust, and L. J. Thénard were possibly made with an impure gas, since their sensations were mainly disagreeable. C. Baskerville and R. Stevenson discussed the preparation and purification of this gas for use as an anæsthetic. If the breathing of the gas be continued, the intoxication stage is quickly passed, unconsciousness and insensibility to pain follows. Hence the gas has long been used as an anæsthetic for small surgical operations, dentistry, etc.; but, owing to the unpleasant after-effects sometimes produced, it is not used so much as formerly. If the breathing of the gas be continued still further, death may ensue. The effects on different people are not always the same. H. Wieland attributed the narcotic effect of nitrous oxide to its interference with the utilization of oxygen by the nerve-cells. M. Nussbaum, P. Bert, C. Winkler, and others have studied the use of this gas as an anæsthetic. L. Hermann said that this gas does not form a compound with hæmoglobin, and cannot do the work of oxygen in respiration, the anæsthetic action is attributed by F. Jolyet and T. Blanche to its displacing the dissolved oxygen in the blood. Small birds are killed by the gas in about 30 seconds; dogs and rabbits in 3–4 minutes. J. Bock found that the lowest fatal press. of the gas for rats is 3 atm., and they are killed by paralysis of the respiratory centre in 8–22 minutes. H. Wieland found the vital activities of the round worm are not affected by nitrous oxide. W. Knop found that young shoots of the *typha latifolia* can grow in an atm. of nitrous oxide, and decompose the gas; indeed, F. Hatton thought that the bacteria in a putrefying extract of meat grow better in nitrous oxide than in air.

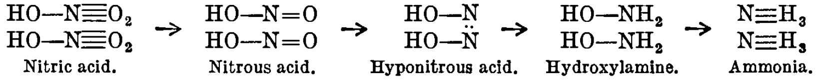
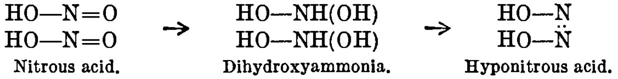
§ 33. Hyponitrous Acid

The reduction of nitrites and nitrates to ammonia readily occurs in alkaline soln. For example, if an excess of sodium or potassium hydroxide be added to nitric acid, the salt is reduced to ammonia by sodium. Intermediate products are formed during the reduction of the nitrate to ammonia. Thus, in 1861, C. F. Schönbein[1] observed the formation of a nitrite when sodium amalgam is the reducing agent, and with the same reducing agent P. de Wilde obtained nitrous oxide, ammonia, and nitrogen as final products. Some years later, E. Frémy, and E. J. Maumené found what was considered to be hydroxylamine among the products of the reduction—a result confirmed later by E. Divers and T. Haga. In 1871, E. Divers discovered the hyponitrites among the products of the reduction, and he also confirmed C. F. Schönbein's observation, for he found a comparatively large proportion of nitrite was sometimes formed during the reduction of nitrates by sodium amalgam. In a general way, E. Divers found that nitrous oxide, N_2O, nitrogen, hydroxylamine, NH_2OH, ammonia, NH_3, sodium hyponitrite, $Na_2N_2O_2$, and sodium hydroxide were always formed during this reaction:



$$\begin{array}{ccccccccc} \text{HO—N}\equiv\text{O}_2 & & \text{HO—N=O} & & \text{HO—N} & & \text{HO—NH}_2 & & \text{N}\equiv\text{H}_3 \\ \text{HO—N}\equiv\text{O}_2 & \rightarrow & \text{HO—N=O} & \rightarrow & \text{HO—}\ddot{\text{N}} & \rightarrow & \text{HO—NH}_2 & \rightarrow & \text{N}\equiv\text{H}_3 \\ \text{Nitric acid.} & & \text{Nitrous acid.} & & \text{Hyponitrous acid.} & & \text{Hydroxylamine.} & & \text{Ammonia.} \end{array}$$

The formation of nitrous oxide and nitrogen is probably the result of secondary or concurrent reactions. According to W. R. Dunstan and T. S. Dymond, the first product of the reduction of sodium nitrite is the hypothetical sodium derivative of *dihydroxyammonia*, $NH(OH)_2$, thus: $2Na+2H_2O+NaNO_2 \rightarrow NaN(OH)_2+2NaOH$; which then condenses to form sodium hyponitrite: $2NaN(OH)_2 \rightarrow 2H_2O+Na_2N_2O_2$; or,



$$\begin{array}{ccccc} \text{HO—N=O} & & \text{HO—NH(OH)} & & \text{HO—N} \\ \text{HO—N=O} & \rightarrow & \text{HO—NH(OH)} & \rightarrow & \text{HO—}\ddot{\text{N}} \\ \text{Nitrous acid.} & & \text{Dihydroxyammonia.} & & \text{Hyponitrous acid.} \end{array}$$

The dihydroxyammonia has not been isolated, and it may or may not be an ephemeral intermediate product. W. R. Dunstan and T. S. Dymond consider that the nitrogen formed in the reduction is the joint effect of hydroxylamine and dihydroxyammonia: $NH_2OH+NH(OH)_2 \rightarrow N_2+3H_2O$. The relative proportions of the reduction products vary greatly within well-defined limits from a maximum down to almost zero.

A maximum yield of *hyponitrites*—eq. to about one-sixth of the total nitrogen—is obtained by using an excess of amalgam, with a conc. soln. (1 : 3) of sodium nitrite, at a temp. below 100°; a maximum yield of *hydroxylamine*—eq. to about 9 per cent. of the nitrogen in the nitrite—is obtained by using a dil. soln. (1 : 50) of sodium nitrite, and keeping the soln. above the amalgam well agitated; to obtain a maximum yield of *nitrous oxide*, the soln. should be kept cool; and for a maximum yield of *nitrogen*, the temp of the soln. should be high; a cold soln. also favours the formation of *ammonia*. Hot dil. soln. give little else than ammonia and nitrogen. So long as any nitrite is present, no hydrogen will appear—except possibly with very dil. aq. soln.

In 1800, H. Davy prepared what he believed to be the potassium salt of nitrous oxide by exposing a mixture of potassium sulphide and hydroxide to nitrous oxide. The sulphide was converted into sulphate, and by solution and crystallization at a low temp., he obtained the compound "mingled with very little potassium carbonate and still less sulphide." The product evolved nitrous oxide when heated, or when treated with carbon dioxide, of sulphuric, hydrochloric, or nitric acid. H. Hess also obtained what may have been silver hyponitrite, by heating barium nitrate, and treating the product with silver salt, and decomposing some of the crystals thus obtained by water.

The preparation of the hyponitrites.—M. L. Nichols and I. A. Derbigny postulated that nitrous oxide in soln. forms hyponitrous acid: $N_2O+H_2O=(HNO)_2$. The several reactions in which hyponitrites are formed can be grouped as follow:

(1) *The reduction of nitrates, nitrites, or nitric oxide.*—In 1871, E. Divers found that when a soln. of sodium nitrite or nitrate is treated with sodium amalgam, the nitrite or nitrate is reduced to sodium hyponitrite: $2NaNO_3+[8H]=4H_2O+Na_2N_2O_2$. The soln. should then be treated with yellow mercuric oxide to destroy the hydroxylamine, and filtered. The alkaline liquid is neutralized by acetic acid, and, when silver nitrate is added, a precipitate of silver hyponitrite, $Ag_2N_2O_2$, is formed. E. Divers prepared sodium hyponitrite by the following process:

Sodium nitrite is dissolved in 3 times its weight of water, and 3 gram-atoms of sodium, in the form of amalgam, per mol of sodium nitrite added in small quantities at a time. The liquid is cooled during the operation. The last quarter of the amalgam is added rapidly, and the flask removed from the cooling bath and agitated. The whole is then violently agitated in a stoppered bottle until a drop of the dil. soln. gives with a drop of silver nitrate and an excess of dil. nitric acid, no blackening due to hydroxylamine. The filtered soln. may smell of ammonia, and this can be removed by exposing the liquid in a dish over sulphuric acid and under reduced press. for a few hours. The liquid is now a conc. soln. of sodium hyponitrite and hydroxide. The filtered soln. when kept at 25°–30° in vacuo over sulphuric acid will deposit the hyponitrite in crystalline granules; if the temp. be below 15°, hydrated sodium hydroxide may be deposited. The hyponitrite may be also precipitated from the soln. by the addition of a large proportion of alcohol.

W. Zorn preferred to use barium nitrite because it is more readily obtained in a state of purity. S. M. Tanatar said the yield is improved if a liquid sodium amalgam is employed. A. Hantzsch and L. Kaufmann found that a 6–7 per cent. yield of silver hyponitrite is obtained if an excess of sodium nitrite be always present. The above process was used by P. de Wilde, and D. H. Jackson. W. Zorn, and E. Divers and T. Haga obtained the hyponitrite when nitric oxide is reduced by an alkaline soln. of stannous chloride: $Sn(OK)_2+2KOH+2NO=K_2SnO_3+H_2O+K_2N_2O_2$; W. R. Dunstan and T. S. Dymond, when an alkali nitrite or nitric oxide is reduced by freshly precipitated ferrous hydroxide suspended in dil. alkali-lye; E. Divers and T. Haga, when hyponitrososulphates are reduced by sodium amalgam; P. C. Ray, when mercuric nitrite is reduced by potassium cyanide: $Hg(NO_2)_2+KCy=HgN_2O_2+2KCyO$—E. Divers had some doubts about this reaction; G. Roederer, when nitric oxide is passed into a soln. of strontium in liquid ammonia, a gelatinous precipitate of strontium hyponitrite is formed which appears as a white powder when the liquid ammonia vaporizes; J. A. Joannis obtained a similar conversion of sodammonium and potassammonium by nitric oxide; E. Weitz and W. Vollmer recommended a soln. of sodium in pyridine: $2Na(C_5H_5N)_2+2NO=Na_2N_2O_2+4C_5H_5N$; and W. Zorn, when alkali nitrites are reduced by electrolysis with a mercury cathode—*e.g.*, barium hyponitrite is formed by the electrolysis of a mixture of equal parts of sodium nitrite and barium acetate with 12 times its weight of water. The reported reduction of nitrites to hyponitrites, by A. E. Menke, by fusion with iron-filings was denied by W. Zorn.

(2) *The condensation of hydroxylamine or of its derivatives with nitrous acid.*—The sodium or silver salt of nitrous acid is usually employed with hydroxylamine chloride or sulphate; the fundamental reaction is symbolized: $NH_2OH+HNO_2=H_2N_2O_2+H_2O$; there is also a secondary reaction resulting in the formation of nitrous oxide: $NH_2OH+HNO_2=N_2O+2H_2O$. S. M. Tanatar warmed potassium nitrite with hydroxylamine chloride at 50° in the presence of calcium hydroxide; the precipitate was decomposed with acetic acid; and the chloride and hyponitrite in the soln. were separated by fractional precipitation with silver nitrate. A. Thum used sodium nitrite, and C. Paal used silver nitrite with hydroxylamine chloride; while W. Wislicenus used hydroxylamine sulphate with sodium nitrite. A. Hantzsch treated a methyl alcoholic soln. of free hydroxylamine with nitrous acid or with nitrous fumes (N_2O_3). A soln. of hydroxycarbaminic acid, HO.CO.NH.OH, in methyl alcohol also gives hyponitrous acid when treated with nitrous acid. L. W. Jones and A. W. Scott obtained sodium hyponitrite by mixing alcoholic soln. of sodium ethoxide (corresponding with 6·62 g. of sodium) and of hydroxylamine hydrochloride (20 g.), cooling, filtering, adding sodium ethoxide soln. (corresponding with 15·4 g. of sodium) to the filtrate, cooling again, and distilling the calculated amount of ethyl nitrite directly into the mixture. The sodium salt is precipitated (yield about 13·5 per cent.).

(3) *The oxidation of hydroxylamine or its derivatives.*—S. S. Kolotoff found that hydroxylamine, NH_2OH, can be oxidized by treatment with sodium hypobromite; A. Thum, by mercuric or silver oxide, or with an alkaline soln. of copper hydroxide; and O. Piloty, by treating hydroxylamine with benzene sulphonic chloride. $C_6H_5.SO_2.Cl$, whereby benzsulphohydroximic acid, $C_6H_5.SO_2.NH.OH$, is formed, and this, when decomposed by treatment with potassium hydroxide, furnishes potassium salts of benzenesulphinic acid, $C_6H_5.SO_2H$, and hyponitrous acid, $H_2N_2O_2$: $2C_6H_5SO_2(NHOH)+4KOH=4H_2O+2C_6H_5SO_2+K_2N_2O_2$. A. Kirschner used the following process:

Fifty grams of hydroxylamine disulphinate—prepared by the action of sulphur dioxide on a soln. of sodium nitrite—are dissolved in 35 c.c. of boiling water. The soln. is cooled by ice, and, while keeping the temp. below 30°, it is mixed with 10 c.c. of a concentrated solution of sodium hydroxide (1 : 1), and 90 c.c. more alkali-lye is then added. The mixture is heated to about 50° for 30–45 minutes, and poured into a litre of water. The undecomposed disulphonate and hydroxylamine are destroyed by adding yellow mercuric oxide, and the clear filtered soln. is made up to four litres and treated with silver nitrate so long as the light yellow silver hyponitrite is precipitated. The precipitate is washed with warm water until it is free from acid.

(4) *The hydrolysis of certain oxyamido-compounds.*—E. Divers and T. Haga showed that hydroxylamido-monosulphonic acid, $HO.NH.HSO_3$, and its salts are hydrolyzed by alkaline soln., forming a sulphite and hyponitrite: $2(HO.NH.HSO_3)+6KOH \rightarrow 6H_2O+2K_2SO_3+K_2N_2O_2$. The hyponitrite is obtained by the following process:

Into a round-bottomed, 250 c.c. flask place 13·8 grms. purified sodium nitrite, 10·6 grms. of anhydrous sodium carbonate, and 58·5 grms. water. When all is dissolved by warming the flask, cool in a mixture of ice and salt, and pass sulphur dioxide through the soln. until the soln. is acid to litmus. Add 0·1 c.c. of sulphuric acid still keeping the temp. below 0° so as to convert the nitrite into hydroximidosulphonate—at higher temp. some nitrilosulphonate is formed. A strong current of air blown through the liquid will remove any sulphur dioxide or nitric oxide present. Warm the soln. to 30° and put in a warm place for a day with the flask corked. Complete hydrolysis to hydroxyamidosulphonate occurs without the formation of hydroxylamine. Add 10·8 grms. of sodium carbonate to neutralize the soln., warming the mixture if necessary to dissolve the salt. Transfer the liquid to a 500 c.c. basin; crush 130–165 grms. of potassium hydroxide in a warm mortar, and grind and dissolve in the liquid in the basin. Let the mixture stand in a warm place for 30 hrs.; if kept over 50 hrs. the quantity of hyponitrite sensibly diminishes. The hyponitrite can be converted into the silver salt so as to separate it from other salts in soln., and the silver hyponitrite afterwards converted into the sodium salt by means of sodium iodide.

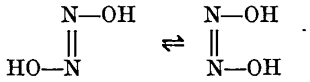
A. Hantzsch found that when dimethyl-nitroso-hydroxy-carbamide, $(CH_3)_2N.CO.N(OH)NO$, or isonitraminecarbamide, is hydrolyzed by alkali-lye at 0°, dimethylamine, carbon dioxide, and alkali hypochlorite are formed. A. Hantzsch and A. Sauer also treated hydroxycarbamide, or dimethylhydroxycarbamide with nitrogen trioxide fumes, and saponified the nitroso-derivatives with alkali-lye. Sodium hydroxide, or sodium ethoxide, was found by H. Wieland to convert styrene pseudonitrosite, $N_2O_2(CHC_6H_5.CH_2.NO_2)_2$, into a mixture of benzaldehyde, nitromethane, alkali hyponitrite, and a little nitrous oxide. It is supposed that the bisnitroso-group is first eliminated producing sodium phenylnitroethanol, $OC_2H_5.CHC_6H_5.CH:NO_2Na$, which further decomposes into benzaldehyde and sodium nitromethane.

The isolation of the free acid.—Although E. Divers prepared various salts of hyponitrous acid in 1871, and W. Zorn prepared the esters—*e.g. diethyl hyponitrite,* $(C_2H_5)_2N_2O_2$—in 1879, anhydrous hyponitrous acid, $H_2N_2O_2$—also called **hyponitrosylic acid**—was not isolated until 1896, when A. Hantzsch and L. Kaufmann obtained it in white crystalline plates, by evaporating the clear soln. obtained by treating silver hyponitrite suspended in dry ether with a soln. of hydrogen chloride in dry ether. Aq. soln. were made by J. D. van der Plaats, in 1877, by treating the silver salt suspended in water, with hydrogen sulphide, hydrochloric, phosphoric, or acetic acid. When an attempt is made to concentrate the aq. soln., it decomposes into water and nitrous acid: $H_2N_2O_2 \rightarrow N_2O+H_2O$. If the dry salt be treated with hydrogen sulphide, the liberated acid is at once decomposed. S. M. Tanatar obtained a soln. of the acid by treating the silver salt, under ether, with hydrochloric acid; on evaporating off the ether, a yellow oil, which did not solidify at —19°, was obtained. This oil was probably a conc. aq. soln., and it often crystallized when allowed to stand in a desiccator under reduced press. When the attempt is made to isolate the acid by the action of hydrogen sulphide on silver hyponitrite, an explosive decomposition occurs.

The properties of hyponitrous acid and the hyponitrites.—The acid forms white crystalline plates which are so unstable that it has not been analyzed. The solid often explodes spontaneously, and also by friction, and by mere contact with solid potassium hydroxide or acid vapours. The solid is readily soluble in water, in alcohol, ether, chloroform, and benzene, but is only sparingly soluble in ligroïn. According to A. Hantzsch and L. Kaufmann, the aq. soln. soon decomposes into water and nitrous oxide; the decomposition is rapid at 25°, and very slow at 0°. J. D. van der Plaats said that if acetic or nitric acid be present, hyponitrous acid can be boiled without decomposition. A. Hantzsch and L. Kaufmann found that the reaction with water is not reversible, and when the rate of decomposition is followed by the usual methods, the results are not in harmony with the equation for a unimolecular reaction, $dx/dt=k(a-x)$, required for $H_2N_2O_2 \rightarrow H_2O+N_2O$, since a number of disturbing side reactions simultaneously occur resulting in the formation of nitric and nitrous acids as well as ammonia. According to A. Hantzsch and L. Kaufmann, the decomposition of hyponitrous acid may occur in three ways: forming in the one case nitrous oxide, $H_2N_2O_2=N_2O+H_2O$; in a second case, hydroxylamine, $3H_2N_2O_2=2NH_2OH+2N_2O$; and in the third case, ammonia, $3H_2N_2O_3=2NH_3+2N_2O_3$. If a reaction catalyzed the third reaction without affecting the first or third, ammonia would be produced without the mediation of hydroxylamine. The electrical conductivity of hyponitrous acid shows that the acid is of about the same strength as carbonic acid, but, as E. Divers showed, it reddens litmus more strongly than carbonic acid, and the colour disappears when the litmus paper is dried. M. Berthelot and P. Petit calculated the heat of formation of hyponitrous acid, in aq. soln., from its elements to be —54·7 Cals. The heat of formation of nitrous oxide is —20·6 Cals., so that in the union of nitrous oxide with water 36·8 Cals. of heat are absorbed. This quantity of heat is greater than the heat of neutralization of hyponitrous acid, and consequently it is not to be expected that nitrous oxide can be converted into a hyponitrite by the action of alkali-lye; but the decomposition of hyponitrites with the evolution of nitrous oxide should be easily effected.

An aq. soln. of hyponitrous acid slowly decomposes into nitrous oxide and water. According to E. Divers, a soln. of one or two grams of acid in a litre of water, at 0°, falls perceptibly in conc. in an hour; and at 25°–30°, it may lose about 17 per cent. of acid in 24 hrs. A. Thum observed a smaller loss. Hyponitrous acid, said E. Divers, is oxidized by nitrous acid, and the stronger oxidizing agents. No way of deoxidizing or hydrogenizing hyponitrous acid is known. It resists attack by sodium amalgam, and, according to A. Thum, by tin and sulphuric acid. W. Zorn said that ethyl hyponitrite is reduced to alcohol and nitrogen by tin and acetic or hydrochloric acid, but since the acid readily decomposes when moist into nitrogen, alcohol, and aldehyde, E. Divers suggested that the alleged reduction is nothing but the hydrogenization of the aldehyde. A. Kirschner said that hyponitrous acid slightly decolorizes iodine-water, but E. Divers showed that this is due to the presence of a trace of sulphite in the acid. According to E. Divers, and A. Thum, a soln. of the free acid does not liberate iodine from potassium iodide. A. Thum said that the acid neither oxidizes hydriodic acid, nor reduces iodine, but J. D. van der Plaats said that starch and potassium iodide test-paper are coloured blue by hyponitrous acid. According to A. Hantzsch and L. Kaufmann, while the pure acid does not liberate iodine from potassium iodide, the mixture liberates iodine after standing some time. This is because the acid breaks down not only into nitrous oxide and water, but it also forms some nitrous acid. Hence, a soln. of silver hyponitrite in conc. sulphuric acid gives the nitrous acid reaction with diphenylamine and ferrous sulphate. J. D. van der Plaats showed that conc. sulphuric acid decomposes hyponitrous acid and its salts, forming nitrous oxide; and A. Hantzsch and L. Kaufmann stated that some nitrogen trioxide and ammonia are formed at the same time: $3H_2N_2O_2=2NH_3+2N_2O_3$; on the other hand, E. Divers, could detect only nitrous oxide and water in the products of the reaction; and A. Hantzsch and A. Sauer added that the nitrogen trioxide and ammonia may have been derived from impurities in the hyponitrite. E. Divers doubts if nitrous acid is ever produced in the spontaneous decomposition of hyponitrous acid. P. C. Ray and A. C. Ganguli showed that hyponitrous acid decomposes simultaneously: $H_2N_2O_2=H_2O+N_2O$, and $5H_2N_2O_2=4H_2O+2HNO_3+4N_2$. The presence of nitric, sulphuric, or hydrochloric acid may have a specific directive influence by favouring one of these reactions; thus, the presence of sulphuric acid gives a larger yield of nitrous oxide. E. Divers found the hyponitrous acid decomposes silver carbonate and possibly also lead and some other carbonates. There is no evidence that carbon dioxide can decompose a hyponitrite. Hyponitrous acid decomposes silver sulphate, nitrate, and chloride. A. Thum said that hyponitrous acid is very stable in the presence of reducing agents. If a soln. of hyponitrous acid be treated with acetic acid and zinc-dust, F. von Brackel recognized the formation of some hydrazine; sodium hydrosulphite also reduces the acid to hydrazine, but not sodium amalgam. Acid or alkaline soln. of potassium permanganate oxidize hyponitrous acid; A. Thum said that in acid soln. nitrous acid is formed, and in alkaline soln., only nitrous acid. A. Kirschner observed that only one gram-atom of oxygen is consumed per mol of hyponitrous acid. Bromine, and hypochlorites also oxidize the acid. M. Coblens and J. K. Bernstein found that when silver hyponitrite is added to an acid soln. of titanous chloride, it is reduced to nitrous oxide but no ammonia is formed; and when the silver hyponitrite is added to an acid soln. of stannous chloride, hydroxylamine is formed. Hence, in the reduction of hyponitrous acid by titanous salts, gases may escape before the reducing agent has a chance to do its full work.

The constitution of hyponitrous acid.—Hyponitrous acid is dibasic. This is illustrated by the mol. wt. determined for the acid by f.p. methods by A. Hantzsch and L. Kaufmann; for ethyl hyponitrite, by W. Zorn; and for the sodium salt, by E. Divers. The dibasicity is further illustrated by the formation of two series of salts: the normal hyponitrites, $R_2N_2O_2$, and the acid hyponitrites or hydrohyponitrites, RHN_2O_2. When an aq. soln. is titrated with alkali, using phenolphthalein as indicator, the red coloration appears when but half the quantity of the base required for the normal salt has been added. These formulæ are also in accord with the analyses. M. Berthelot and J. Ogier's analyses—$Ag_4N_4O_5$ for the silver salt, and N_4O_3 for the anhydride—were probably made with impure materials. According to W. Zorn, the reduction of diethyl hyponitrite with sodium amalgam, or tin and hydrochloric acid, furnishes alcohol with some aldehyde: $(C_2H_5)_2N_2O_2+H_2=N_2+2C_2H_5OH$—*vide supra.* This is taken to show that the ethyl groups are not directly attached to the nitrogen atoms but have intermediate oxygen atoms, $C_2H_5.O.N:N.O.C_2H_5$, otherwise some amine, $C_6H_5.NH_2$, or imide, $(C_2H_5)_2:NH$, would be formed. Hence also the free acid is probably HO.N : N.OH, corresponding with the substitution of the bivalent oxygen of nitrous oxide with two univalent hydroxyl groups. This constitution is also in agreement with the assumption that hyponitrous acid is a *diazohydroxide.* A. Hantzsch argued that because nitramide, $NH_2.NO_2$, is obtained by the hydrolysis of nitrocarbamic acid, $NO_2.NH.COOH$, that is, $HO.CO.N_2O_2H$, and hyponitrous acid is a product of the hydrolysis of isonitraminecarbamide $(CH_3)_2N.CO.N_2O_2H$, as indicated above, therefore nitramide and hyponitrous acid have a similar structure: HO—N=N—OH. Owing to the greater ease with which nitramide and its salts break down with the evolution of nitrous oxide, A. Hantzsch also argues that nitramide in the syn-acid, and hyponitrous acid is the anti-acid. Certainly, the acid character of nitramide is in strong contrast with the other inorganic amides, and the fact that it breaks down into nitrous oxide leaves its structural identity with an assumed amide of nitric acid, *viz.*, $H_2N.NO_2$, an open question. It is therefore conceivable that the molecule may have two different structures represented graphically by



$$\begin{array}{r} \text{N—OH} \\ \| \\ \text{HO—N} \end{array} \rightleftharpoons \begin{array}{l} \text{N—OH} \\ \| \\ \text{N—OH} \end{array}$$

Anti-form. Syn-form.

This means that with our present system of representing the composition of compounds, the hydroxyl groups in hyponitrous acid may be disposed on the same side of the molecule—the **syn or cis** (*cis*, on this side of) **type**; or on opposite sides of the molecule—the **anti or trans** (*trans*, across) **type.** Evidence of the possible existence of organic derivatives of three types are known:

$$\begin{array}{l} C_6H_5\text{—N} \\ \quad R\text{—N} \end{array}$$

Syn-diazo-compounds.

$$\begin{array}{l} C_6H_5\text{—N} \\ \qquad\ \ \text{N—R} \end{array}$$

Anti-diazo-compounds.

$$\begin{array}{l} C_6H_5\text{—N—R} \\ \qquad\ \ \text{N} \end{array}$$

Diazonium-compounds.

The dehydration of the syn-form of hyponitrous acid is supposed by A. Hantzsch to furnish nitrous oxide. H. Henstock gave for the electronic structure:

$$\overset{+}{H}\text{—}\overset{-}{O}\text{—}\overset{+}{N}=\overset{+}{N}\text{—}\overset{-}{O}\text{—}\overset{+}{H}$$

In the analytical determination of the hyponitrites, W. Zorn treated soln. of the free acid, or of its salts in cold dil. nitric acid with an excess of silver nitrate, and just neutralized the free acid with ammonia or sodium carbonate. The washed and dried precipitate was weighed as silver hyponitrite, or weighed as metal or chloride. A. Thum treated the aq. soln. of the acid with an excess of a soln. of permanganate, and in 15 minutes added sulphuric acid; after standing for another hour the soln. was warmed to 30°, and treated with a known quantity of $0{\cdot}1N$-oxalic acid sufficient to decolorize the permanganate. The excess oxalic acid was determined by permanganate titration. A. Hantzsch and A. Sauer, and

A. Kirschner did not obtain good results by the permanganate process, as E. Divers showed, but they did not follow A. Thum's directions closely.

§ 34. The Hyponitrites

According to A. Hantzsch and L. Kaufmann,[1] if dry ammonia be passed into the ethereal soln. of hyponitrous acid, **ammonium hydrohyponitrite**, $(NH_4)HN_2O_2$, or $NH_4O.N:N.OH$, is formed in colourless crystals which melt with turbulent decomposition at 64°–65°. The salt spontaneously decomposes into ammonia, nitrous oxide, and water. The salt dissolves in water with an alkaline reaction. **Ammonium hyponitrite**, $NH_4O.N:H.ONH_4$, cannot be prepared directly, but D. H. Jackson (1893) made it by treating silver hyponitrite with an alcoholic soln. of ammonium sulphide, and evaporating the filtered liquid in vacuo over sulphuric acid. Ammonium hyponitrite furnishes long needle-like crystals readily soluble in water and in alcohol. W. Zorn, D. H. Jackson, W. Wislicenus, E. Divers, E. Divers and T. Haga, J. A. Joannis, and A. Hantzsch and L. Kaufmann prepared **pentahydrated sodium hyponitrite**, $Na_2N_2O_2.5H_2O$, by methods indicated in connection with the acid. W. Zorn also obtained it by the electrolysis of a soln. of sodium nitrate, or better, sodium nitrite, using a mercury cathode. The hydrated sodium hyponitrite occurs in small crystals; and when deposited from a conc. soln. of alkali hydroxide, it has a granular appearance. The aq. soln. on evaporation in vacuo does not yield crystals. E. Weitz and W. Vollmer obtained yellow crystals of the *enneahydrate*, $Na_2N_2O_2.9H_2O$; and they prepared sodium hyponitrite by the action of soln. of sodium or pyridine on nitric oxide. A. W. Scott prepared non-hygroscopic sodium hypontrite as follows:

> To a sat. soln. of 3·26 grms. of hydroxylamine hydrochloride in anhydrous ethyl alcohol at −5° is added slightly more than the calculated amount of sodium dissolved in the least amount of alcohol. After filtering, 110 c.c. of anhydrous ether and 3·24 grms. of sodium in the minimum amount of alcohol are added to the soln., which is then cooled

to $-5°$ and twice the calculated amount of either amyl or propyl nitrite added. After being kept at $-5°$ for 1 hour, the sodium hyponitrite is collected, washed with alcohol, then with ether, and dried over sulphuric acid in vacuo; the yield is 13·9 per cent.

The anhydrous **sodium hyponitrite,** $Na_2N_2O_2$, is obtained by dehydrating the hydrate in vacuo. There is, at the same time, a slight loss of nitrous oxide. The product resembles magnesia alba. Heat is evolved when the anydrous salt dissolves in water, and it is insoluble in alcohol. The anhydrous salt only slowly takes up water from a soln. of sodium hyponitrite. Heated in a closely covered vessel, it yields nitrogen and sodium oxide mixed with some nitrate: $3Na_2N_2O_2=2N_2+2Na_2O+2NaNO_2$. The salt bears a heat of 300° without decomposing, and then melts and effervesces; glass, platinum, and even silver are freely attacked by the fused mass, and the product hisses when water is added to it. Sodium hydroxide and nitrite are the solid products when the hydrated salt is quickly heated, and nitrous oxide, as well as nitrogen, is given off. Conc. sulphuric acid decomposes the salt, with the production of odourless, white vapours, and no nitrosylsulphate is formed if the sodium salt is pure. The salt, or a fairly conc. soln. of it, effervesces with a dil. acid like a carbonate. It dissolves a little silver hyponitrite and decomposes silver chloride. Dry sodium hyponitrite is not decomposed by carbon dioxide, and, since the hydrated or dissolved salt partly decomposes by interaction with the water, its power of fixing carbon dioxide does not indicate that it is directly decomposable by that substance. The soln., when boiled, decomposes moderately fast into hydroxide and nitrous oxide. If allowed to stand for a day, a trace of nitrite is formed. According to W. Zorn, A. Thum, and A. Hantzsch and L. Kaufmann, the conductivity of the aq. soln. decreases with time owing to the hydrolysis. If the free acid be neutralized with sodium hydroxide using phenolphthalein as indicator, the composition corresponds with **sodium hydrohyponitrite,** $NaHN_2O_2$. The soln. readily decomposes into sodium hydroxide and nitrous oxide.

W. Zorn, J. A. Joannis, E. Divers and T. Haga, and E. Divers prepared **potassium hyponitrite,** $K_2N_2O_2$, by the methods employed for the sodium salt indicated in connection with the preparation of the acid. E. Divers said the preparation of this salt is less satisfactory than is that of the sodium salt. Potassium hyponitrite can be precipitated incompletely from its aq. soln. in the anhydrous form by alcohol, and there is a loss during the washing with alcohol. He also treated silver hyponitrite with the calculated quantity of potassium iodide, and rapidly evaporated the soln. in vacuo, subsequent to precipitation by alcohol. The salt is partially decomposed during these operations. The minute, prismatic crystals of potassium hyponitrite decompose more readily than the sodium salt, but are stable if quite dry; they are soluble in 90 per cent. alcohol, aad sparingly soluble in absolute alcohol. E. Divers observed that aq. soln. of alkali hyponitrites decompose slowly into nitrous oxide and alkali hydroxide—gradually in the cold, rapidly when heated. Alkali hydroxides impede the decomposition, and if in conc. soln., stop it. The neutralization of the alkali by carbon dioxide hastens the decomposition, but this is not due to the decomposition of the hyponitrite by the carbon dioxide. M. Berthelot gave for the heat of neutralization ($H_2N_2O_2$aq., 2KOHaq.)=15·6 Cals. H. Stamm measured the solubility of the sodium salt in aq. ammonia.

E. Divers prepared the basic salt **cupric hydroxyhyponitrite,** $Cu_2(OH)_2N_2O_2$, according to A. Thum. This salt was also made by S. S. Kolotoff, A. Thum, and A. Kirschner. It is obtained by adding sodium hyponitrite to a soln. of a cupric salt. The acid liquor so obtained deposits more salt when neutralized. A small quantity of this salt is precipitated when an excess of cupric sulphate is added to a soln. of hydroxylamine sulphate, and then a little ammonia. The sea-green salt is very stable; it gives water, a mixture of cupric and cuprous oxides, and nitric and nitrous oxides when heated. The salt can be boiled with water without losing its colour, but it is decomposed by a soln. of sodium hydroxide. It is soluble in dil. acids and aq. ammonia. E. Divers tried unsuccessfully to make **cuprous**

hyponitrite by treating sodium hyponitrite with cupric sulphate in the presence of free hydroxylamine. Cuprous oxide is first precipitated, and then by aerial oxidation, the basic cupric hydroxyhyponitrite is formed. S. S. Kolotoff claimed to have made **dihydrated cuprous hyponitrite,** $Cu_2N_2O_2.2H_2O$, by oxidizing hydroxylamine by sodium hypobromite, and treating the product with cupric sulphate. G. T. Morgan and F. H. Burstall obtained evidence of the formation of copper trisethylenediaminohyponitrite, $[Cu\ en_3]N_2O_2$, by the action of silver hyponitrite on copper in the presence of ethylenediamine. E. Divers made **silver hyponitrite,** $Ag_2N_2O_2$, or **nitrosyl silver,** as previously indicated. The salt was also made by W. Zorn, J. D. van der Plaats, H. Wieland, A. Hantzsch and L. Kaufmann, M. Berthelot and J. Ogier, O. Piloty, and E. Divers and T. Haga. The methods employed are indicated in connection with the preparation of the acid. P. Sabatier and J. B. Senderens could not make it by the union of nitric oxide and silver at any temp. tried. E. Divers recommended the following process for preparing silver hyponitrite:

A conc. soln. of sodium hyponitrite and hydroxide is diluted and mixed with sufficient silver sulphate or nitrate in dil. aq. soln. (1 : 210) to precipitate the hyponitrite. The soln. may or may not be neutralized with acetic acid before adding the silver salt. The mixture is stirred vigorously to convert silver oxide into hyponitrite. When the precipitate has nearly all subsided, the turbid liquor of bright yellow is decanted and again treated with the silver salt until, after stirring well, brownish-silver oxide remains. The whole is then mixed and left to settle. A good light is necessary to judge the colours, but light should be avoided as much as possible. The precipitate is washed by decantation, and stirred up with successive portions of dil. sulphuric acid (1 : 250), until the acid fails to become neutral and shows a slight yellow opalescence when mixed with a drop of a soln. of sodium carbonate. The precipitate is then washed by decantation with water until free from sulphate; then with water containing a trace of sodium carbonate; and finally with water. It is then collected on a filter, dried in vacuo, and then heated to 100° in dry air. The salt can be purified before drying by dissolving it in small portions at a time, in ice-cold dil. sulphuric acid (1 : 333); the filtered soln. is made alkaline with sodium carbonate, and the precipitate washed with dil. sulphuric acid, etc., as before. Silver nitrate is employed at the start if it is essential to keep nitrates from the final product; for the washing re-precipitation, etc., are but imperfect means of purifying the precipitate. Sodium carbonate is preferable to aq. ammonia for precipitating the salt because, as A. Hantzsch and L. Kaufmann found, the last trace of ammonia is difficult to wash from the silver salt; and silver carbonate is at the same time excluded because of its solubility in the excess of carbon dioxide always present in the soln.

Silver hyponitrite is bright yellow, and if pale in colour it generally contains a trace of ammonia, or some silver oxide. If black silver suboxide is present, the colour may be greyish-yellow, and with other impurities present, the colour may be bright green. There is no evidence that the difference in colour is due to the presence of allotropic forms. When precipitated from strongly alkaline soln., or from conc. soln. of the sodium and silver salts, the precipitate is compact, and dense, but if precipitated from dil. soln., it is flocculent and bulky. A. Kirschner, and C. Paal and F. Kretschmer, obtained crystals of silver hyponitrite by deposition from the ammoniacal soln., either by evaporation or by dilution with water. M. Berthelot and J. Ogier gave —9·3 Cals. for the heat of formation. E. Divers stated silver hyponitrate is decomposed by a moderate heat into nitric oxide, silver, and a little silver nitrate; it does not fuse or exhibit any change other than the passage from a bright yellow to a silver-white colour. J. D. van der Plaats said that silver hyponitrite decomposes explosively when heated—but, added E. Divers, this preparation probably contained some acetate. A. Thum found that the bright yellow salt when heated becomes brown before assuming the silvery white colour; and A. Kirschner said that it is temporarily black. E. Divers attributes the brown or black coloration to the dense, red, almost opaque fumes of nitrogen peroxide emitted by the decomposing salt, and possibly to the presence of some sulphite. A. Thum detected no silver nitrate among the products of decomposition, but found that nitrogen peroxide is produced. E. Divers then demonstrated that nitrogen, nitric oxide, nitrogen peroxide, silver, silver nitrate, and possibly a trace of nitrite are produced during the decomposition. The first action is represented: $2Ag_2N_2O_2=4Ag+N_2+2NO_2$. The presence of silver nitrate is attributed to the action of nitrogen peroxide on the undecomposed hyponitrite: $Ag_2N_2O_2+4NO_2=2AgNO_3+4NO$; and the silver nitrate and nitric oxide interact: $AgNO_3+NO=Ag+2NO_2$. P. C. Ray and A. C. Ganguli found that the equation: $3Ag_2N_2O_2=4Ag+2AgNO_3+2N_2$ is not supported by analytical data. They represent the action $2Ag_2N_2O_2=2Ag_2O+2N_2O$—with $2Ag_2O=4Ag+O_2$; also $Ag_2N_2O_2=2Ag+2NO$—with $2NO+O=N_2O_3$; $2N_2O_3+Ag=AgNO_3+3NO$; and $5Ag_2N_2O_2=2AgNO_3+(8Ag+2O_2)+4N_2$. The production of the nitrous fumes is thus attributed to a secondary reaction. E. Divers does not accept these conclusions. E. Divers, and A. Kirschner regard the nitrogen peroxide as a direct product of the heating of the salt; and E. Divers assumes nitric oxide to be a product of a series of complex reactions, here it is regarded as a direct product of the decomposition of the hyponitrite.

According to E. Divers, moist silver hyponitrite is not stable, for it very slowly decomposes at ordinary temp.; light and heat quicken the change. The salt thus loses its bright colour, and contains some nitrite and nitrate. The production of a nitrite occurs in a few hours if the salt be exposed to bright diffused light, and in a few minutes in sunlight. When the purified yellow hyponitrite, under water, is exposed to light, a brown flocculent substance is formed on the surface. If a black or grey colour is obtained, impurities were present in the hyponitrite. Silver hyponitrite is least sensitive to light when dry and exposed to dry air. The slight atmospheric oxidation of moist silver hyponitrite observed by E. Divers and T. Haga is attributed by E. Divers to the slow production of nitric oxide which is retained as nitrite and nitrate by the salt, and not to the direct oxidation of the salt. Silver hyponitrite is more soluble in water than silver chloride, and, added A. Thum, the salt is not affected by boiling water. A. Thum, and E. Divers found that the salt is dissolved by dil. nitric or sulphuric acid and can be recovered by quickly neutralizing the acid with alkali. The sulphuric acid soln. soon deposits silver sulphate. Cold acetic acid dissolves silver hyponitrite sparingly; and it is only slightly soluble in phosphoric acid. According to P. C. Ray and A. C. Ganguli, the decomposition of silver hyponitrite by mineral acids at 25°–29° results in the liberation of hyponitrous acid, which then decomposes according to the equation: $H_2N_2O_2=H_2O+N_2O$; and $5H_2N_2O_2=4H_2O+2HNO_3+4N_2$. The products with silver hyponitrite are:

Nitrogen as . . .	N_2	NHO_3	N_2O	Total
Using nitric acid . .	7·25	1·81	1·26	10·32 per cent.
Using hydrochloric acid .	6·95	1·74	1·61	10·30 ,,
Using sulphuric acid . .	4·52	1·13	4·58	10·23 ,,

According to E. Divers, silver hyponitrite is dissolved by aq. ammonia, but only sparingly if dil.; the hyponitrite can be recovered by neutralizing or dissipating the ammonia. Silver hyponitrite is also soluble in soln. of ammonium carbonate or nitrate; in aq. hyponitrous acid; and in a soln. of alkali hyponitrite. Silver hyponitrite is readily oxidized by conc. nitric acid; conc. sulphuric acid acts energetically, and the heat of the reaction is sufficient to decompose some of the salt, forming nitrosyl sulphate, and nitrogen peroxide. The salt is not decomposed by a cold soln. of sodium carbonate; it is not decomposed by a cold dil. soln. of sodium hydroxide; it is completely decomposed by an eq. amount of a soln. of potassium iodide; it is imperfectly decomposed by a soln. of sodium chloride unless in considerable excess—when a soln. of sodium chloride is shaken with an excess of silver hypochlorite, decomposition ceases when the soln. contains 4 eq. of sodium chloride to 5 eq. of sodium hyponitrite; the addition of absolute alcohol effects a partial separation of the two sodium salts. According to A. Thum, silver hyponitrite absorbs dry hydrogen sulphide at 0° without giving off any water or gas; but after some time, an explosive decomposition occurs with the production of light and heat, and the evolution of reddish-brown fumes. Hydrogen sulphide, and phosphoric acid set free hyponitrous acid. It is not attacked by acetic acid; and carbon dioxide does not decompose it.

W. Zorn, A. Kirschner, and E. Divers prepared **tetrahydrated barium hyponitrite,** $BaN_2O_2.4H_2O$, by adding barium chloride to a conc. soln. of sodium hyponitrite; and A. Guntz and R. C. Mentrel found that what was assumed to be the hyponitrite is formed when a soln. of barium in liquid ammonia at —50° is treated with nitrogen peroxide. On dissipating the ammonia, the gelatinous precipitate dries to a white powder. The product was hydrated by exposure to moist air, and decomposed by water with the evolution of nitric oxide. The crystals are but sparingly soluble in water, and are slowly decomposed by cold water, rapidly by hot water. Carbon dioxide of the atm. decomposes the dry salt. It is readily soluble in dil. acetic acid, and when the acid is neutralized by ammonia or baryta-water, the salt is precipitated unchanged. L. Maquenne suspended silver hyponitrite in water, and added enough nitric acid to dissolve about one-third the hyponitrite; the mixture was then agitated with a soln. of barium chloride. The precipitate was filtered and washed; and the filtrate treated with ammonia to obtain more hyponitrite. The precipitate was washed with alcohol, then with ether, and finally dried over sulphuric acid. A. Kirschner mixed ammoniacal soln. of silver hyponitrite and barium nitrate, and washed the precipitate with alcohol and ether. The product corresponded with **hydrated barium hyponitrite,** $BaN_2O_2.H_2O$. W. Zorn obtained **barium hydrohyponitrite,** $BaH_2(N_2O_2)_2$, by adding the calculated quantity of sulphuric acid to barium hyponitrite suspended in water; or by neutralizing the acid with baryta-water and rapidly evaporating under reduced press. The salt readily decomposes with the evolution of nitrous oxide, and the product is accordingly impure. The needle-like crystals are very soluble in water. G. Roederer, as indicated in connection with the acid, obtained **strontium hyponitrite,** SrN_2O_2, by the action of nitric oxide on a soln. of strontium in liquid ammonia. The gelatinous precipitate furnishes a white powder when the ammonia is dissipated. A. Kirschner, and L. Maquenne also prepared **pentahydrated strontium hyponitrite,** $SrN_2O_2.5H_2O$, by the methods employed for the hydrated barium salt. L. Maquenne said that the strontium salt is more stable than the calcium salt, and gives off no gas in vacuo at 100°; it loses water less readily than the barium salt, and, unlike L. Maquenne, A. Kirschner could not obtain the anhydrous salt by heating the hydrate to 100°. L. Maquenne, A. Kirschner, and E. Divers prepared **tetrahydrated calcium hyponitrite,** $CaN_2O_2.4H_2O$, by the methods they employed for the barium salt. L. Maquenne said that the dry salt does not decompose at 100°, but the moist salt slowly decomposes at that temp. It is very sparingly soluble in water, soluble in dil. acids, and in acetic acid, whilst ammonia re-precipitates the unchanged salt from acid soln. The salt is decomposed by sulphuric acid (1 : 1), with the evolution of gas. On account of its stability, E. Divers said that it is a good hyponitrite to keep in stock.

A. E. Menke observed a white precipitate of **magnesium hyponitrite** when a magnesium salt is treated with sodium hyponitrite; **zinc hyponitrite** is formed in an analogous way. Both salts are soluble in acetic acid. According to E. Divers, if sodium nitrite be reduced with sodium amalgam, and neutralized with acetic acid, a greyish-black deposit of mercury is formed on the addition of mercurous nitrate, and not mercurous hyponitrite. This is due to the presence of hydroxylamine with the hyponitrite soln. E. Divers said that **mercurous hyponitrite,** $Hg_2N_2O_2$, is precipitated by adding a soln. of sodium hyponitrite, free from hydroxylamine, to a soln. of mercurous nitrate as in the case of mercuric hyponitrite. P. C. Ray added that the sodium hyponitrite soln. should be neutralized since the precipitate will otherwise be contaminated with mercurous oxide. A. Thum treated the mercurous nitrate soln. with acid potassium hyponitrite; and P. C. Ray obtained it by adding a dil. soln. of sodium hyponitrite to a soln. of mercurous and mercuric nitrites, and obtained a flocculent yellow precipitate of mercurous hyponitrite. No oxide is precipitated from the soln. of mercurous nitrite soln

The bright yellow salt is washed by suction, and dried over sulphuric acid. E. Divers found that the salt is stable, but is blackened by light. A. Thum said that it is blackened in direct sunlight owing to the separation of mercurous oxide. When heated, E. Divers said that it is decomposed, forming mercuric salt, and when further heated, it decomposes like the mercuric salt: $Hg_2N_2O_2=2Hg+2NO$; $Hg_2N_2O_2=Hg+HgO+N_2O$; or $3Hg_2N_2O_2=4Hg+2HgNO_3+2N_2$. A. Thum said that the salt blackens at a little below 100°, and at a higher temp., forms red mercuric oxide. P. C. Ray and A. C. Ganguli found that mercurous hyponitrite begins to decompose slowly at 80°, and on raising the temp. it assumes a black colour, and at 150°, becomes reddish-yellow and decomposition ceases; the temp. can then be raised to 200° without the production of any visible nitrous fumes. There is no evidence that the decomposition proceeds: $Hg_2N_2O_2=2HgO+N_2$, for the actual proportion of nitrogen produced is very small. The main products are mercury and mercuric oxide with nitric and nitrous oxides—the proportion of nitrogen and mercurous nitrate is small and probably an effect of secondary reactions. Thus:

Nitrogen as . . .	N_2	N_2O	NO	Total
Per cent.	0·47	2·22	2·65	6·03

P. C. Ray and A. C. Ganguli represent the reaction as a kind of tautomeric process, half the oxygen being oxylic, Hg.O.N : N.O.Hg=Hg_2O+N_2O and $Hg_2O=HgO+O$; and half imidic, Hg.N : O=Hg+NO. The actual amount of nitrogen formed is almost equal to that existing as mercurous nitrate so that the reaction: $4Hg_2N_2O_2=2HgNO_3+6Hg+N_2+2N_2O$ is more likely than the simpler one: $3Hg_2N_2O_2=2HgNO_3+4Hg+2N_2$. E. Divers said that mercurous hyponitrite is blackened even by very dil. soln. of alkali hydroxides, and it dissolves readily in dil. nitric acid, and can be re-precipitated from the soln. by cautious neutralization with sodium carbonate. According to P. C. Ray, the nitric acid soln. of mercurous hyponitrite immediately becomes opalescent from the separation of mercury which remains at first in a fine state of suspension; if, however, the soln. be set aside for an hour or so, the mercury settles at the bottom, and there is a slow and continuous effervescence owing to the liberation of nitrous oxide; consequently, the salt is partially decomposed in the nitric acid soln.: $Hg_2N_2O_2=Hg+Hg(NO)_2$, and that when the nitric acid soln. is treated with alkali-lye some mercurous oxide is precipitated. P. C. Ray and A. C. Ganguli found that on the decomposition of the salt by the action of nitric, hydrochloric, and sulphuric acids, as in the case of silver hyponitrite, the hyponitrous acid is liberated and decomposed according to the simultaneous equations: $H_2N_2O_2=N_2O+H_2O$; and $5H_2N_2O_2=4H_2O+2HNO_3+4N_2$. The percentage composition of the gases with the different acids was:

Nitrogen as . . .	N_2	NHO_3	N_2O	Total
Using nitric acid . .	3·55	0·89	0·56	5·0
Using hydrochloric acid .	3·76	0·94	1·51	6·21
Using sulphuric acid . .	1·60	0·40	2·98	4·98

so that the presence of the mineral acid has a specific directive influence in determining the course of the reaction. E. Divers explained the incompleteness of the decomposition with sulphuric acid by the low solubility of the mercurous sulphate. He said nitric oxide, and nitrogen trioxide or peroxide are produced by the oxidizing action of the less stable oxides.

According to E. Divers, normal **mercuric hyponitrite**, HgN_2O_2, is obtained by precipitation from sodium hyponitrite and mercuric nitrate. The mixed soln. of sodium hydroxide and hyponitrite obtained by reducing sodium nitrite with sodium amalgam is diluted and almost neutralized by dil. nitric acid keeping the soln. ice-cold all the time. It is then poured into a soln. of mercuric nitrate which must not be in excess, and should contain as little free acid as possible. The slightly turbid mother-liquor is decanted from the precipitate, and, after being neutralized with sodium carbonate, is mixed with more mercuric nitrate, and poured back on the main precipitate; after agitation the mixture is allowed to settle, and the mother-liquor decanted off the precipitate which should be washed quickly by decantation since it is liable to be quickly destroyed by the acid mother-liquor. Mercuric hyponitrite is a flocculent, cream-coloured precipitate, which is easily washed on the filter, and dries to a pale, buff powder—the colour is probably due to an incipient change to the mercurous salt. If dried on a porous tile, it seems to be *trihydrated*, $HgN_2O_2.3H_2O$, but if dried in a desiccator it is anhydrous. The salt is sensitive to light and should be dried in the dark. A soln. of mercuric nitrite or chloride, however highly dilute, always yields mercuric hyponitrite, when treated with sodium hyponitrite in the presence of potassium sulphate, whereas mercuric nitrate under similar conditions gives the basic sulphate, $2HgO.HgSO_4.\frac{1}{2}H_2O$. P. C. Ray, therefore, assumes that the nitrogen is attached to the mercury in the nitrite, but in the nitrate, it must be united to oxygen. Mercuric hyponitrite is decomposed by heat into mercuric oxide, and nitrous oxide, and also into metal and nitric oxide. It dissolves in hydrochloric acid, and in sodium chloride soln., but, being unstable, it changes into the mercurous salt so that the soln. is liable to become turbid. P. C. Ray showed that dil. hydrochloric acid readily dissolves mercuric hyponitrite in the cold, and the salt is re-precipitated when the soln. is neutralized by an alkali. Potassium hydroxide at once decomposes mercuric hyponitrite into oxide without forming basic salts; in very dil. alkali-lye, the precipitate is slightly soluble. P. C. Ray found that mercuric hyponitrite dissolves with difficulty as such in dil. nitric acid, and with still greater difficulty in boiling conc. nitric acid, the hyponitrite is re-precipitated on adding an alkali. Slowly or quickly, mercuric hyponitrite decomposes into mercurous hyponitrite and nitric oxide, and some of the latter is oxidized by air converting some hyponitrite into nitrate. E. Divers added that no other mercuric salt decomposes into the mercurous salt, although many cupric salts change to cuprous salts; ferric oxalate also changes to ferrous oxalate and carbon dioxide. P. C. Ray described some basic mercuric hyponitrites; thus trihydrated **mercuric trioxyhyponitrite,** $3HgO.HgN_2O_2.3H_2O$, or $3Hg(OH)_2.HgN_2O_2$, is formed by dropping a very dil. soln. of sodium hyponitrite (free from hydroxylamine) to a mixed soln. of mercurous and mercuric nitrites containing sodium chloride to eliminate the mercurous mercury. If the order of mixing be reversed, or if too much hyponitrite be used at once, the precipitate turns grey or even black. The flocculent yellow precipitate was washed and dried. It is also obtained by adding a soln. of sodium hyponitrite to one of mercuric chloride. The yellowish powder is sparingly soluble in dil. or conc. nitric acid, and easily soluble in warm dil. hydrochloric acid. The pentahydrate was obtained by adding a soln. of sodium hypochlorite to a soln. of mercuric nitrate containing as little as possible free nitric acid. Pentahydrated **mercuric pentoxytrihyponitrite,** $5HgO.3HgN_2O_2.5H_2O$, or $5Hg(OH)_2.3HgN_2O_2$, was obtained by adding potassium cyanide to a neutral soln. of mercurous and mercuric nitrates mixed with just enough sodium chloride to remove mercurous mercury, but no chloride should be in excess: $Hg(NO_2)_2+KCy=HgN_2O_2+2KCyO$. The precipitate is washed with water, and dried in darkness over sulphuric acid. The soln. of the salt in warm dil. hydrochloric acid, when neutralized with alkali hydroxide, gives a voluminous precipitate.

A. E. Menke found **aluminium hyponitrite** is formed as a white precipitate when sodium hyponitrite is added to a soln. of an aluminium salt. It is insoluble in water, and in acetic acid. The precipitate of **cerium hyponitrite** obtained in an analogous way is soluble in acetic acid; likewise also **tin hyponitrite,** which is insoluble in acetic acid; and lead hyponitrite. E. Divers, A. Thum, and A. Kirschner prepared **lead hyponitrite,** PbN_2O_2, by the action of a soln. of sodium hyponitrite on a lead salt. The precipitate at first is cream coloured and flocculent, but it soon becomes sulphur-yellow, and the dense, cream-coloured salt is probably a hydrate; A. Kirschner, said E. Divers, mistook it for a basic salt *lead oxyhyponitrite*, $PbO.PbN_2O_2$. A. Thum found that when formed in a dil. acid soln., the salt is crystalline. It is soluble in dil. nitric acid, and decomposed by sodium hydroxide, but not by a cold soln. of sodium carbonate.

A. E. Menke prepared **bismuth hyponitrite** as a white precipitate by adding sodium hyponitrite to a soln. of a bismuth salt. It is insoluble in acetic acid. The analogous precipitates of white **manganese hyponitrite,** red **cobalt hyponitrite,** and of green **nickel hyponitrite** are soluble in acetic acid. With ferrous salts, olive-green **ferrous hyponitrite** is formed, it is insoluble in water, and becomes yellow when treated with acetic acid. With ferric salts, yellow **ferric hyponitrite** is formed—insoluble in water, soluble in acetic acid. With potassium salts, **platinum hyponitrite** is formed which is less soluble in acetic acid than it is in water.

§ 35. Nitric Oxide

Early in the seventeenth century, J. B. van Helmont[1] obtained a *spiritus sylvestris* by the action of nitric acid on the metals, he also applied the same name to carbon dioxide; but it is scarcely conceivable that he could have considered the two gases to be the same form of matter even though they were parts of the general chaos. About the middle of the seventeenth century, J. Mayow also prepared the same gas by the action of nitric acid on iron, but he did not study its specific properties; a similar remark applies to C. Huyghens and N. Papin, who made it by the action of nitric acid on copper; and to R. Boyle, who made it by the action of nitric acid on iron or silver and mentioned that it forms red fumes by contact with atm. air. This was confirmed by G. E. Stahl at the beginning of the eighteenth century. S. Hales prepared the gas by the action of nitric acid on mercury, iron-filings, or pyrites. J. Priestley, however, is generally credited with the discovery of the gas. It is true that he prepared it by the action of nitric acid on copper as others had done previously, but he showed that the gas has a number of specific properties and is veritably a chemical individual. He also employed its property of reacting with the oxygen of the atmosphere to form a soluble gas in the volumetric analysis of air (*q.v.*). In **1777**, A. L. Brongniart prepared the gas by the action of nitric acid on organic substances. J. Priestley called the gas *nitrous air;* and both he, and F. Fontana regarded the gas as nitric acid surcharged with phlogiston. H. Cavendish showed that the gas contained oxygen and nitrogen; and at the beginning of the nineteenth century, its composition was established by H. Davy, and J. L. Gay Lussac and L. J. Thénard. In conformity with the antiphlogistic notation, the gas was called *oxyde d'azote*, or **nitric oxide**, NO.

The preparation of nitric oxide.—Nitric oxide is usually regarded as the first product of the oxidation of nitrogen although under certain conditions nitrous oxide (*q.v.*) may be formed. W. Manchot [2] found that it is produced along with ozone by the silent electric discharge in air, and that its production lowers the yield of ozone. It is formed under numerous other conditions. Thus, F. Fischer and H. Marx, W. Nernst, W. Muthmann and H. Hofer, and F. Haber and co-workers obtained it along with ozone when air is led over a glowing Nernst's filament; or past the high potential, alternating current arc; by electric sparks in air; by white-hot surfaces; and by burning hydrocarbons, carbon monoxide, or hydrogen. A. Reis found nitric oxide in the ammonia-oxygen flame. A. Wolokitin found that by working at a press. of 20 atm., a greater proportion of nitric oxide is produced than when the press. is normal. H. Kämmerer found that it is also produced when magnesium burns in air—*vide supra*, fixation of nitrogen. O. F. Tower obtained traces of nitric oxide when a mixture of nitrogen and water vapour is passed over a Nernst's filament at about 2000°. This subject has been discussed in connection with the fixation of nitrogen. The formation of nitric oxide during the oxidation of hydrogen cyanide, in the presence of a platinum catalyst, has been discussed by J. Zawadzky and J. Wolmer, and L. Andrussoff. R. Hara and H. Shinozaki found that with a platinum catalyst a maximum yield of 85 to 95 per cent. is obtained at 800°. The oxidation begins at about 500°. The best conc. of hydrogen cyanide is 4 to 8 per cent.; higher conc. give solid products—cyamelide and cyanuric acid—as well. It is supposed that the hydrogen cyanide, HCy, is first oxidized to cyanic acid, HCyO, and, on further oxidation, this forms water, carbon monoxide, and nitric oxide. If there is a shortage of oxygen, the cyanic acid polymerizes to $(HCyO)_3$ or $(HCyO)_n$. The formation of nitric oxide by the oxidation of ammonia is discussed in connection with that gas. I. Milner obtained nitric oxide during the oxidation of ammonia (*q.v.*) by manganese dioxide, ferric oxide, etc. B. Tacke, and A. J. Lebedeff found nitric oxide to be formed by the action of the *bacterium hartlebii* on nitrates. F. Wöhler found that nitric oxide is produced by heating a mixture of boron nitride and a metal oxide. U. Sborgi and co-workers found that the yield of nitric oxide obtained varies greatly with these different samples and also with the nature of the admixed oxide. With the oxides Fe_2O_3, Ni_2O_3, Co_2O_3, MnO_2, Mn_3O_4, and CuO, yields as high as 72 per cent. are given, and the residue remaining after the reaction gives an increased yield of nitric oxide with a fresh quantity of boron nitride; this result is repeated four or five times, the yield increasing each time until the residue becomes converted into a compact mass.

Nitric oxide is formed during the electro-reduction of nitric acid; G. Brüning employed a current of 5 to 10 amps. at ordinary temp. with nitric acid of 20 to 30 per cent. concentration, according to the electrodes and other conditions employed. At higher temp., nitrogen peroxide is simultaneously produced, and by varying the conditions other products can be obtained. Nitric oxide is also formed, by treatment of nitric acid, nitrous acid, or nitrogen peroxide with reducing agents like carbon, phosphorus, sulphur, organic compounds, many metals, the lower oxides of the metals, and metal salts. It is also formed when nitrogen peroxide is treated with water; or when nitrogen peroxide is heated above 600°. F. Raschig obtained it as a product of the action of nitrous oxide on nitrous acid, and F. Emich, by the action of a mixture of sulphuric acid with 2 per cent. of sodium nitrite on mercury. L. Moser recommended this process, and also the reduction of nitrous acid with hydriodic acid. The gas can be purified by absorbing it in a conc. soln. of ferrous sulphate, and driving it out again by gentle heat. The gas can also be absorbed by a soln. of potassium permanganate or dichromate. R. W. Gray purified nitric oxide by the fractional distillation of the liquefied gas. Nitric oxide is usually prepared by the reduction of nitric acid. Thus,

N. A. E. Millon obtained it by the action of copper, bismuth, lead, silver, or mercury on nitric acid of sp. gr. 1·2 to 1·3. The more dil. the acid, the lower the temp. at which it reacts, and the less is the gas contaminated with free nitrogen. Copper treated with dil. nitric acid under conditions where the rise of temp. is prevented by a freezing mixture, yields a gas so pure that it is all absorbed by a soln. of ferrous sulphate. The reaction between nitric acid and copper was studied by J. H. Niemann, etc.—*vide* the action of this acid on the respective metals. The preparation of nitric oxide by the action of copper on nitric acid has been discussed by L. Carius, A. Senier, H. Kämmerer, J. J. Acworth, and H. Moissan. The initial and final products of the reaction are represented by $3Cu+8HNO_3=3Cu(NO_3)_2+4H_2O+2NO$. G. Lunge said that nitric oxide is almost the only gaseous product obtained by the action of nitric acid of sp. gr. 1·2 on arsenic trioxide. Ferrous sulphate reacts with warm nitric acid, or a mixture of sodium nitrate and dil. sulphuric acid, forming nitric oxide. M. Coblenz and J. K. Bernstein found that nitric oxide is formed, but no ammonia, when sodium nitrite is added drop by drop to an acid soln. of titanous chloride, and when nitric acid is treated with a soln of stannous chloride containing a drop of ferrous sulphate. J. Pelouze, and J. L. Gay Lussac obtained nitric oxide by the interaction of potassium nitrate and a warm soln. of ferrous chloride in dil. hydrochloric acid : $2NaNO_3+6FeCl_2+8HCl=6FeCl_3+2NaCl+4H_2O+2NO$.

J. Thiele said that fairly pure nitric oxide is produced when a conc. soln. of sodium nitrite is dropped into a hydrochloric acid soln. of ferrous chloride or sulphate. Since commercial sodium nitrite usually contains some carbonate, it is recommended that this impurity be removed by treating the soln. with calcium chloride. J. Matuschek found that with a mixture of soln. of sodium nitrite and ferric chloride, nitrogen peroxide and nitric oxide are formed, and that by passing the mixed gases through water the nitrogen peroxide is decomposed into nitric acid and nitric oxide: $FeCl_3+3NaNO_2=3NaCl+Fe(NO_2)_3$, and $2Fe(NO_2)_3+3H_2O=2Fe(OH)_3+3NO_2+3NO$. If the sodium nitrite be placed under carbon disulphide, and a suspension of hydrated ferric chloride in the same solvent be added, the nitrogen peroxide which is formed remains dissolved in the carbon disulphide. L. Moser recommended preparing the gas of a high degree of purity by reducing with mercury a soln. of nitrous acid in sulphuric acid, or by allowing nitrous and hydriodic acids to interact. W. A. Noyes said that nearly pure nitric oxide is rapidly generated by dropping conc. sulphuric acid on to sodium nitrite covered with two or three times its weight of water: $3HNO_2=HNO_3+2NO+H_2O$. By washing the gas with conc. sulphuric acid or water the trace of nitrogen dioxide present is removed. C. M. van Deventer dropped a mixture of potassium nitrite and ferrocyanide into dil. acetic acid: $K_4FeCy_6+HNO_2+CH_3COOH=K_3FeCy_6+H_2O+CH_3.COOK+NO$. R. Weber obtained nitric oxide of a high degree of purity by passing sulphur dioxide into warm nitric acid of sp. gr. 1·15 : $2HNO_3+3SO_2+2H_2O=3H_2SO_4+2NO$. A. Wagner obtained nitric oxide by the action of acids on a mixture of potassium nitrate and sodium sulphite ; and by heating a mixture of potassium nitrate and carbonate in the presence of chromic oxide, manganese oxide, cuprous oxide, or stannous oxide; and M. Chikachigé, by heating a soln. of cobalt nitrate and potassium thiocyanate. S. Abe and R. Hara found that cyanogen can be readily oxidized to nitric oxide by air in the presence of platinum as a catalytic agent.

The physical properties of nitric oxide.—Nitric oxide is a colourless gas at ordinary temp. R. W. Gray said that the liquid is blue ; but K. Adwentowsky[3] found liquid nitric oxide to be colourless in thin layers, but light blue in thick layers, but it is thought that its blue colour is due to the presence of traces of nitrogen trioxide which cannot be removed by fractionation. The liquid can be frozen to a colourless, or a snow-like solid. T. Thomson gave 1·041 for the **relative density** of the gas ; F. Delaroche and J. E. Bérard, 1·0888 ; and H. Davy, 1·093 ; more recent determinations by G. Daccomo and V. Meyer gave 1·0372 ; P. A. Guye and

C. Davila gave 1·0367. The literature was reviewed by M. S. Blanchard and S. F. Pickering. K. Adwentowsky found the **specific gravity** of the liquid at the b.p. is 1·269. R. W. Gray found the **weight of a litre** of nitric oxide gas at n.p. θ to be 1·3402 grms.—the observed data varied from 1·3398 to 1·3408 grms. G. D. Liveing and J. Dewar gave 1·255 for the **specific gravity** of the liquid at the b.p. J. S. Stas found the **molecular weight** to be 29·97 ; P. A. Guye and C. Davila, 30·012. H. Henstock, R. T. Birge, and A. O. Rankine discussed the **electronic structure.** T. Graham, F. Exner, W. Sutherland, A. Naumann, and J. H. Jeans calculated the mol constants at 0°. The **molecular velocity** is 43,900 cms. per sec. ; the **free path,** 903×10^{-8} cm. ; and the **molecular diameter,** 16×10^{-9} cm. to 26×10^{-9} cm. A. Balandin found the mol. vol. to be 23·6 ; and E. Rabinowitsch gave 23·7. E. Moles, G. Kirsch, and P. N. Pavloff studied this subject.
